Abstract

This paper studies the effects of recessions on U.S. local labor markets. Using variation in sudden employment losses during each recession between 1973 and 2009 and an event study approach, we find that areas more affected by recessions experience highly persistent declines in employment, indicating that these places face long-lasting declines in labor demand. Recessions also lead to persistent decreases in population, primarily due to lower in-migration. Most importantly, and contrary to prior work, every recession we study generates local labor market hysteresis in the form of persistent decreases in the employment-population ratio and earnings per capita. Our results imply that recessions induce persistent reallocation of employment across space, and that limited population responses result in longer-lasting disruptions to local labor markets than previously thought.

JEL Classification Codes: I24, I26, J24, J31

Keywords: recessions, hysteresis, local labor markets, event study

1 Introduction

Recessions receive enormous attention from researchers, policymakers, and the public. Most of this attention focuses on short-run changes in nationwide measures like the unemployment rate and GDP. These outcomes are clearly important, but many of the broader consequences of recessions remain uncertain. One topic that has received comparatively little attention is how recessions affect local labor markets. The value of understanding how recessions shape local areas is underscored by growing evidence that place-specific factors shape intergenerational mobility (Chetty and Hendren, 2018*a,b*), health (Finkelstein, Gentzkow and Williams, 2019), voting (Charles and Stephens, 2013; Autor et al., 2016), and many other outcomes.

This paper studies the impacts of every U.S. recession between 1973 and 2009 on local labor markets.¹ Specifically, we study how employment, population, and earnings evolve in local areas (metropolitan areas and commuting zones) where national recessions are more versus less severe. We draw upon multiple data sources, including those from the Bureau of Economic Analysis and Census Bureau, to create annual panels of longitudinally-harmonized geographic areas stretching over five decades. We estimate event study models that relate the evolution of local economic activity to sudden employment changes that arise during recessions, while controlling for secular trends in population growth. This empirical strategy allows us to examine flexibly whether recessions have temporary or persistent impacts on local labor markets.

We find that declines in employment which emerge during recessions are extremely persistent. Moreover, these employment losses tend to grow over time. Across the five recessions that we study, a 5 percent decrease in metro area employment during the recession, about the median for the Great Recession, on average leads to a 6.2 percent decrease in employment 7–9 years after the recession trough. During and immediately after recessions, the employment decline is driven by manufacturing and construction, two procyclical sectors. In the longer term, employment falls relative to less-affected areas by a similar amount across all industries, including services, trade,

¹These recessions took place from 1973–1975, 1980–1982 (we pool the very short recession in 1980 with the longer one in 1981–1982), 1990–1991, 2001, and 2007–2009.

and government. Moreover, the sudden decreases in employment that occur during recessions are not associated with differential pre-trends beforehand. These results imply that areas which suffer a more severe recession experience a *persistent* relative decrease in labor demand.

The consequences of this employment decline depend on the extent of population adjustment. We find evidence of population declines that begin during recessions and continue to grow for several years after the recession trough. Using IRS data to examine in- and out-migration after the 2001 and 2007–2009 recessions, we find that the population decline stems entirely from reduced in-migration to severely hit areas, with out-migration actually falling after these recessions. The post-recession decrease in population is persistent, but smaller than the decrease in employment.

Due to this limited population response, each recession leads to local labor market hysteresis in the form of persistently lower employment rates. On average, a 5 percent decrease in employment during a recession leads to a 3.2 percent (2 percentage point) decrease in the employment-population ratio. This effect accounts for about 55 percent of the decline in local area employment 7–9 years after trough, with the decline in population explaining the remaining 45 percent. Moreover, local labor market hysteresis persists for several decades. As of 2017, we continue to find reduced local employment rates for every recession we study.

Each recession also leads to local hysteresis through lasting decreases in earnings per capita. On average, a 5 percent decrease in employment during a recession leads to a 3.2 percent decrease in earnings per capita 7–9 years after the recession trough. Using individual-level data from the decennial Census and American Community Survey, we find that earnings decline throughout the distribution, but effects tend to be more severe at the bottom and middle. Over two-thirds of the medium-term decline in annual earnings arises from a reduction in hourly wages.

One possible explanation for local labor market hysteresis is a change in the composition of residents or jobs following a recession. We see a persistent increase in the share of residents age 65 and above and a decrease in the share of residents age 15–39, but the size of these impacts are modest. Following the 1973–1975, 1990–1991, and 2007–2009 recessions, we observe a decrease in the share of workers employed in managerial, professional, and technical occupations and an

increase in the share in manual and service jobs. For these same recessions, we also see a decrease in the share of residents with a college degree and an increase in the share with no more than a high school degree. For the 1980–1982 and 2001 recessions, there is less evidence of a shift in occupational or educational composition. The fact that we find local labor market hysteresis for all recessions, but a change in education and occupation shares for only three, suggests that composition changes are not the key drivers. Indeed, when we estimate recession impacts on demographically-adjusted local labor market aggregates, we conclude that changes in education, age, sex, and race/ethnicity explain less than half of the overall impacts on average earnings. Instead, local labor market hysteresis appears to stem mainly from lasting impacts on individuals, consistent with evidence on the effects of job displacement (e.g., Jacobson, LaLonde and Sullivan, 1993; Lachowska, Mas and Woodbury, 2020) and the Great Recession (Yagan, 2019).

Our results differ from a series of influential papers that suggest that most recessions would not lead to local labor market hysteresis. In particular, Blanchard and Katz (1992) estimate vector autoregressions (VARs) and find that the unemployment rate, labor force participation rate, and wages return to trend within ten years of a decline in local labor demand. Using the same methodology, Dao, Furceri and Loungani (2017) estimate a similar degree of medium-run convergence in more recent data, while Yagan (2019) finds similarly rapid recovery following the 1980–1982 and 1990–1991 recessions, but slower recovery from the more severe Great Recession.² Using empirically-relevant Monte Carlo simulations, we show that finite sample bias arising from a limited number of time series observations leads VARs estimated in prior work to incorrectly imply convergence in the presence of hysteresis. This finite sample bias, which would be of first-order importance even if researchers had access to 100 years of data, explains the difference in our results from those reported by Blanchard and Katz (1992) and other authors using the same VAR methodology. Evidence of finite sample bias also helps clarify a longstanding debate initiated by

²Dao, Furceri and Loungani (2017) use a different source of identification and find that population is less responsive in the short run. In addition to examining the implications of the Blanchard and Katz (1992) model for recovery of states following recessions, Yagan (2019) uses tax data to show that individuals living in areas severely affected by the Great Recession suffered enduring employment and earnings losses regardless of whether they stayed or moved locations.

the landmark studies of Bartik (1991) and Blanchard and Katz (1992) on whether shifts in labor demand lead to local labor market hysteresis.

Thus, the key contribution of this paper is new, compelling evidence on how recessions have affected local labor markets over the past 50 years. Our results show that recessions not only generate lasting shifts in the spatial distribution of employment and population, but that relative reductions in employment rates and earnings also last longer than previously thought. Moreover, the impacts of recessions on local labor markets have changed little over the past five decades. This similarity is remarkable, given the different macroeconomic drivers of the recessions and secular changes in business dynamics (Haltiwanger, 2012; Decker et al., 2016), mobility (Molloy, Smith and Wozniak, 2011, 2014), and demographics (Shrestha and Heisler, 2011). Even recessions that are less severe in aggregate terms, such as those in 1990–1991 or 2001, have lasting effects on local areas. These results underscore the extent to which local hysteresis is a general feature of the U.S. economy.

Our work complements several other studies that examine how local labor demand shifts, such as a change in manufacturing jobs, affect earnings, employment, and population (e.g., Bound and Holzer, 2000; Notowidigdo, 2013; Freedman, 2017; Amior and Manning, 2018; Beaudry, Green and Sand, 2018; Garin, 2019; Gathmann, Helm and Schönberg, 2020). These papers do not study recessions but instead generally focus on changes in jobs over one- or ten-year horizons across all phases of the business cycle.³ As a result, these studies provide limited guidance on the short- and long-run effects of recessions on local areas.⁴ Additional evidence is particularly valuable because of the disagreement in the literature over whether shifts in local labor demand have persistent

³An important exception is Monras (2020), who provides empirical evidence that reduced in-migration accounts for essentially all of the population decline in areas hit harder by the Great Recession and develops a structural model to rationalize this fact. Our findings on in-migration are qualitatively similar. We differ from Monras (2020) in our examination of multiple recessions and greater breadth of economic outcomes.

⁴Amior and Manning (2018) also show that population responds imperfectly to local labor demand shifts, leading to persistent gaps in employment rates. We differ in our use of sudden shifts in local labor demand that arise during recessions and our use of annual data, as compared to their analysis of predicted employment changes based on industrial structure (Bartik, 1991) using decadal data. A key advantage of our empirical setting and flexible regression models is that we can provide direct evidence that the severity of different recessions is not strongly correlated over time—it is not the case that on average the same areas experience particularly large employment losses during each recession—even though the *effects* of recessions are persistent.

effects on wages and employment, and how, when, and why these relationships may have changed (Bartik, 1993, 2015; Austin, Glaeser and Summers, 2018). Greenstone and Looney (2010) and Stuart (2018) provide evidence that recessions lead to persistent declines in per-capita earnings at the county level; our analysis goes considerably further, by examining a larger range of outcomes, other levels of geography, and additional business cycles.

We emphasize that our finding of local labor market hysteresis is not inconsistent with aggregate economic recovery (e.g., Dupraz, Nakamura and Steinsson, 2020; Hall and Kudlyak, 2020). The cross-sectional identifying variation we use permits an implicit counterfactual of how a local labor market that experienced a severe employment loss during a recession would have evolved had it experienced a less severe employment loss.⁵ A persistent relative decline does not imply that an area fails to recover in an absolute sense, but rather that a gap remains between that area and one that experienced a less severe recession. These relative impacts most directly shed light on the distributional consequences of recessions and the efficiency costs associated with incomplete local labor market adjustments.

2 Conceptual Framework

To guide our empirical analysis, we describe how recessions might affect local labor markets. Our starting point is that labor demand falls during recessions. This decrease could stem from many possible sources, such as an increase in interest rates or oil prices, or a consumption decline driven by expectations or animal spirits. The decline in labor demand generally differs across local labor markets, possibly because of differences in industrial specialization or the types of tasks performed.

A decline in local labor demand during the recession may or may not persist afterwards. If the decline in labor demand is only temporary, then employment, employment rates, and wages would fall during the recession and return to their previous trend afterwards. This pattern would arise if firms temporarily laid off workers or reduced their hours, and individuals did not move across

⁵Other papers studying local labor markets also identify relative effects (e.g., Blanchard and Katz, 1992; Autor, Dorn and Hanson, 2013; Amior and Manning, 2018).

labor markets in the short run.

On the other hand, the decline in local labor demand could persist, possibly because employers change their production process (Jaimovich and Siu, 2015; Hershbein and Kahn, 2018) or shut down (Foster, Grim and Haltiwanger, 2016). A decrease in employment also could persist because of local multipliers—in which the initial employment reduction is amplified by a cascade of falling consumer demand—or agglomeration effects—in which firms face higher non-wage costs or lower productivity when nearby firms reduce their employment (e.g., Greenstone, Hornbeck and Moretti, 2010; Kline and Moretti, 2014; Gathmann, Helm and Schönberg, 2020; Helm, 2020; Howard, 2020).⁶ Although the short-term dynamics are similar for a temporary or persistent decline in labor demand, the latter generates a lasting decline in employment. The response of other variables depends on the elasticities of labor supply within and across local labor markets. If labor supply is perfectly elastic, then wages and employment rates return to their prior trend (Blanchard and Katz, 1992). If labor supply is less than perfectly elastic, then wages and employment rates remain depressed.

This framework implicitly assumes there is only one type of worker. Worker heterogeneity can also generate persistent declines in economic activity. For example, if high-income workers are more likely to leave an area in response to a decline in labor demand (Bound and Holzer, 2000; Wozniak, 2010; Notowidigdo, 2013), then average wages might fall simply because of a change in worker composition. If younger workers are more likely to leave an area or are less likely to move in after a decline in labor demand (Molloy, Smith and Wozniak, 2011), then the average employment rate might fall. Firm heterogeneity also could generate persistent declines in economic activity (e.g., if large, high-paying firms are more likely to relocate or shut down).

This simple framework yields several takeaways. First, we expect to see temporary declines

⁶The possibility of a persistent decline in local labor demand relates to the relative importance of agglomeration and locational fundamentals as determinants of economic geography. Davis and Weinstein (2002, 2008) find striking evidence of a recovery in Japanese city population and manufacturing employment following Allied bombings in World War II. These results suggest that rationalizing a persistent decline in local labor demand would require that fundamentals change during recessions. This might seem surprising, but the presence of adjustment costs could diminish firms' responses to secular changes, and firms might pay these adjustment costs during recessions (Foote, 1998). Moreover, there is some disagreement about the relative importance of fundamentals and agglomeration (e.g., Bosker et al., 2007; Miguel and Roland, 2011; Michaels and Rauch, 2018).

in employment, employment rates, and wages in areas that experience a more severe recession. Second, a persistent decline in employment indicates a persistent decline in local labor demand. Third, the responsiveness of population influences whether employment rates and wages recover or remain persistently lower. Finally, changes in worker composition could partly explain any persistent changes in employment rates and wages. Guided by these implications, we next describe our strategy for estimating how recessions affect local labor markets.

3 Data and Empirical Strategy

3.1 Data

We compile several public-use data sets to measure local economic activity. These data sets are constructed by government agencies using administrative data. Employment is available from the Bureau of Economic Analysis Regional Economic Accounts (BEAR), Census County Business Patterns (CBP), and Quarterly Census of Employment and Wages (QCEW).⁷ BEAR and CBP data are available starting in 1969, while QCEW data are available from 1975-onward. BEAR data also contain aggregate earnings. We use the National Cancer Institute’s Surveillance, Epidemiology, and End Results (SEER) data for annual population estimates, which are available by sex, race, and age. To measure in- and out-migration, we use the Internal Revenue Service Statistics of Income (SOI) data.⁸ Finally, we use tabulations and microdata from the decennial Census and the American Community Survey (ACS) to examine the earnings distribution and composition changes.⁹

⁷Because employment counts are often suppressed for small counties and industries in CBP data, we adopt the imputation procedure of Holmes and Stevens (2002) when necessary. Details are in the Data Appendix. Results from this approach agree closely with WholeData, which uses a linear programming algorithm to recover suppressed employment estimates (Bartik et al., 2019).

⁸SOI data are available starting in the 1990s. Although they capture moves only for tax filers, SOI data are considered a high-quality source for point-to-point migration flows and have been used in several papers (e.g., Kaplan and Schulhofer-Wohl, 2012, 2017; Wilson, 2018). We use a version of these data compiled by Janine Billadello of Baruch College’s Geospatial Data Lab (Billadello, 2018).

⁹We use versions of these tabular and microdata from NHGIS and IPUMS, respectively (Manson et al., 2019; Ruggles et al., 2019). The Data Appendix describes the processing of these data and how we link individuals to our geographies of interest. We also explored using the Current Population Survey, which contains many of the same demographic items as the Census and ACS and provides meaningful substate geography indicators starting in 1989

With the exceptions of the decennial Census and ACS microdata, all of the data sets are available at the county level. The Census and ACS are available at the Public Use Microdata Area (PUMA) level, which we map to other geographies using crosswalks available from the Geocorr program of the Missouri Census Data Center. Consequently, we can examine the effects of recessions at multiple levels of geography: metropolitan area and commuting zone.¹⁰ Metropolitan areas and commuting zones are commonly used to approximate local labor markets, although there is some disagreement as to which provides the better approximation (Foote, Kutzbach and Vilhuber, 2017).¹¹ Both types of areas are composed of counties, so it is straightforward to map our county-level data into metro areas or commuting zones. A slight complication is that definitions of metropolitan areas and commuting zones change over time; we use Core Based Statistical Areas (CBSAs) as defined by OMB in 2003 (reflecting the 2000 Census), and commuting zones also based on the 2000 Census. Although we focus on metro areas because of their greater size and thicker labor markets, we show that our main results are robust to using commuting zones, which unlike metro areas cover the entire United States.¹²

3.2 Empirical Strategy

Our empirical strategy relies on cross-sectional variation in sudden employment changes that occur during nationwide recessions. We use this variation to estimate the impacts of a decline in labor demand on local labor market outcomes, separately for each recession.

One natural approach is to estimate the event study regression

$$y_{i,t} = s_i \delta_t + x_{i,t} \beta + \mu_i + \varepsilon_{i,t}, \quad (1)$$

in the basic monthly files. Changes in sampling result in relatively few areas with sufficient sample sizes to offer meaningful analysis.

¹⁰We do not examine counties because these are often too small to constitute local labor markets, our area of focus.

¹¹Metropolitan statistical areas are defined by the Office of Management and Budget (OMB) as having “at least one urbanized area of 50,000 or more population, plus adjacent territory that has a high degree of social and economic integration with the core as measured by commuting ties” (Office of Management and Budget, 2003). Commuting zones are defined based on commuting patterns and do not have a minimum population threshold or urban requirement (Tolbert and Sizer, 1996).

¹²Metro areas, consistently defined, cover 80–90 percent of people and jobs throughout our sample, with this share growing over time.

where $y_{i,t}$ is a measure of local economic activity in location i and year t ; s_i is the severity of the recession, measured as the log employment change in location i from the nationwide peak to trough (multiplied by -1); $x_{i,t}$ is a vector of control variables; and μ_i is a location fixed effect that absorbs time-invariant differences across locations. The key parameter of interest is δ_t , which describes the relationship between the change in employment during the recession and local economic activity in year t . The inclusion of location fixed effects means that one of the δ_t coefficients must be normalized; we do this two years before the nationwide peak because the exact timing of recessions is uncertain and there is variation in when aggregate economic indicators decline.¹³ This specification allows the sudden decline in employment during the recession to have impacts which vary flexibly across years, transparently showing both pre-trends and dynamic effects.

An important issue with estimating equation (1) in our setting is that log employment is both an outcome of interest and used to construct the key independent variable, s_i . This can introduce a mechanical correlation between $y_{i,t}$ and s_i , so that estimates of δ_t for all years are inconsistent.¹⁴ Instead, we estimate

$$y_{i,t} = s_i \delta_t + x_{i,t} \beta + y_{i,t_0-2} \gamma_t + \varepsilon_{i,t}. \quad (2)$$

Equation (2) does not include location fixed effects, but instead controls for time-invariant cross-sectional differences using the dependent variable two years before the nationwide business cycle peak, y_{i,t_0-2} . We allow the coefficient γ_t to vary by year to increase the flexibility of this control. Unlike equation (1), estimates of δ_t from equation (2) generally are consistent under the null hypothesis of a random walk process.

¹³Because we show the entire range of estimates of δ_t , it is straightforward to see how our estimates would change with a different normalization year.

¹⁴To see this problem, consider normalizing $\delta_t = 0$ for the peak year, t_0 . Equation (1) then can be rewritten

$$y_{i,t} - y_{i,t_0} = (y_{i,t_1} - y_{i,t_0}) \delta_t + (x_{i,t} - x_{i,t_0}) \beta + (\varepsilon_{i,t} - \varepsilon_{i,t_0}),$$

where $s_i \equiv -(y_{i,t_1} - y_{i,t_0})$. It is straightforward to show that, if $y_{i,t}$ follows a stationary random walk, the probability limit of $\hat{\delta}_t$ equals -0.5 for all years except the trough year, when the coefficient equals -1 mechanically. We mitigate this problem by normalizing δ_t two years before the peak, but still prefer equation (2) because it has better properties for any choice of normalization year and can be extended to control for a vector of lagged dependent variables.

We measure local recession severity using annual employment data from BEAR.¹⁵ We modify NBER recession peak and trough dates to account for our use of annual data. Specifically, we construct s_i using the log employment change for each geography between 1973–1975, 1979–1982, 1989–1991, 2000–2002, and 2007–2009.¹⁶ Using fixed national timings for each recession, rather than location-specific peak-to-trough periods, introduces some measurement error but minimizes the risk of endogeneity. We use wage and salary employment (private and public) to measure recession severity, as coverage of the self-employed is incomplete and varies over time.

The specification in equation (2) captures the initial effect of the decline in labor demand, along with subsequent demand and supply responses. The key identifying assumption is that local recession severity, s_i , is exogenous to unobserved changes in local labor market outcomes, $\varepsilon_{i,t}$, conditional on the controls in the regression. In addition to controlling for time-invariant differences across local areas, we include several variables in $x_{i,t}$ to bolster the credibility of this assumption. First, we include Census division-by-year fixed effects to flexibly capture broader changes in economic conditions and demographics. Second, we control for interactions between pre-recession population growth and year indicators to adjust for secular changes in population and demographics.¹⁷ A key possible violation of our identifying assumption is the presence of pre-trends in local economic activity that are correlated with recession severity. Fortunately, estimates of δ_t for pre-recession years allow us to directly examine the presence of such pre-trends. We cluster our standard errors at the metro or commuting zone level to allow for arbitrary autocorrelation in the error term $\varepsilon_{i,t}$.

The parameter vector $\{\delta_t\}$ describes the time-varying relative effects of recessions on local labor markets. A negative value of δ_t in post-recession years implies that economic activity falls

¹⁵QCEW is an alternative. While quarterly data would allow us to use the NBER recession quarters to measure recession severity, they would also require a seasonal adjustment. In practice, as we show below, results are robust to using either source to measure severity.

¹⁶The NBER recession dates are November 1973 to March 1975, January 1980 to July 1980, July 1981 to November 1982, July 1990 to March 1991, March to November 2001, and December 2007 to June 2009.

¹⁷We control for the log change in population age 0–14, 15–39, 40–64, and 65 and above. We construct these population variables using SEER data, which are available starting in 1969. The pre-recession population growth years are 1969–1973 (for the 1973–1975 recession), 1969–1979 (for the 1980–1982 recession), 1979–1989 (for the 1990–1992 recession), 1990–2000 (for the 2001 recession), and 1997–2007 (for the 2007–2009 recession).

in areas that experience a more severe recession, relative to what would have happened if they experienced a less severe recession. For example, although aggregate employment trended upward throughout our sample period, estimates of δ_t do not reflect this aggregate movement, as changes in economic activity at the division-year level are absorbed by fixed effects.

3.3 The Severity of Recessions Across Time and Space

Before moving to estimates of equation (2), we describe the characteristics of the five recessions that are our focus. Figure 1 displays aggregate seasonally adjusted, nonfarm employment from the Current Employment Statistics from 1969 to 2017. Nationwide employment more than doubled over this period. This growth was interrupted by five recessions (combining the two in the early 1980s), as indicated by the vertical shaded bars in the graph. While there is little consensus on the macroeconomic causes of each recession, the drivers almost certainly differ (Temin, 1998). The 1973–1975 and 1980–1982 recessions followed increases in the price of oil and subsequent increases in interest rates by the Federal Reserve. There is less agreement on the causes of the 1990–1991 recession (Temin, 1998) or the 2001 recession. The 2007–2009 recession followed tumult in housing and financial markets.

Using annual data from BEAR, Table 1 shows the national changes in employment from peak to trough for each recession, both overall and for major industrial sectors.¹⁸ The recessions vary greatly in overall magnitude, from a 3 percent employment decline during the Great Recession to a 1 percent increase from 1989–1991, with the others falling in between. Manufacturing and construction usually experience the largest employment decline, with the exception of construction during the 2001 recession, which was accompanied by a housing boom. The impact on other industries varies widely across recessions. The early 1990s downturn and the Great Recession were broad in scope, with most major industries experiencing an employment decline. The early 1980s recession was heavily concentrated in certain industries, including manufacturing and construction. Similarly, the mid-1970s recession and the one in 2001 saw flat or rising employment in several

¹⁸We use BEAR data rather than national Current Employment Statistics data to be consistent with our subsequent analysis, but the patterns are qualitatively similar.

industries, including the relatively large services sector. Our use of annual BEAR data masks some of the severe employment losses that are evident in monthly data.

These patterns suggest that areas with employment bases reliant on manufacturing and/or construction were more likely to suffer severe recessions, although the variation across recessions in other industries implies that it is not necessarily the same areas being hit each time. Figure 2 shows the severity of each recession (as captured by log employment change) across metropolitan areas. While many areas in the Midwest Rust Belt fare poorly in each recession, there is considerable heterogeneity for other areas. The Northeast, for example, is severely affected in the 1970s, 1990s, and 2001, but only modestly in the early 1980s and late 2000s. The Pacific Northwest fares relatively well in the 1970s and 1990s but is hit harder in the other three recessions. There is also ample variation across areas in severity within a given recession, with several areas actually gaining employment in each episode.¹⁹

Figure 3 displays the frequency with which a given area experienced a severe recession over the sample horizon. We define a metropolitan area as having a severe recession if it experienced a log employment change worse than the median area for a given recession. The Detroit and Chicago metros, for example, experienced downturns worse than the median for all five recessions, while the Houston metro did so only in 2001. The distribution in severity frequency is roughly symmetric, with a similar number of metros experiencing zero or one severe recession (109) as those experiencing four or five (103).

We show the serial correlation in recession severity in Table 2. Panel A shows the raw correlations across metros in log employment changes for each pair of recessions. As suggested by Figures 2 and 3, the serial correlation is positive, but moderate. Consistent with the different origins of the recessions as well as temporal changes in industrial mix, the pattern is not monotonic across time. Notably, the Great Recession is basically uncorrelated with the previous two recessions, and the early 1990s recession is uncorrelated with the early 1980s recession. We also show in Panel B the correlations within each of the nine Census divisions (i.e., after partialing out divi-

¹⁹Panels A and B of Appendix Figure A.1 present kernel densities of the demeaned and unadjusted log employment changes across metros for each recession.

sion fixed effects), and in Panel C the correlations after additionally controlling for pre-recession population growth. These controls tend to slightly reduce the magnitudes of the correlations, but positive serial correlation remains in a few cases. Our event study approach will reveal whether this serial correlation affects the estimates. We also control for the severity of previous recessions as an additional robustness check and show that these additional controls do not appreciably change the results.

Table 3 describes the characteristics of metro areas that experience a more versus less severe recession (defined as whether the log employment change is above or below the median). We measure these characteristics using the closest decennial Census to the recession start year, except for the 2007–2009 recession, which is measured using the 2005–2009 ACS. Recessions tend to be more severe in places with higher population but slower pre-recession population growth, higher employment rates and earnings per capita, a higher manufacturing employment share, and a less educated workforce. The largest difference between areas that experience a more versus less severe recession is the manufacturing employment share, though this difference has decreased considerably over time. Moreover, many of the differences are quite small. The variables in Table 3 include both sources of recession severity and factors that might influence the response of local areas to reductions in labor demand. We estimate impacts directly on some of these variables, while also examining effects on worker composition to better understand mechanisms.²⁰

4 The Impacts of Recessions on Local Labor Markets

4.1 Employment

We begin with estimates of equation (2) for log employment in metro areas. Each panel in Figure 4 shows separate estimates for each recession. We include four years before the start of the recession to capture any pre-trends, and we follow areas for up to 10 years after the trough. Specification 1, shown in red (circles), includes only Census division-by-year fixed effects in $x_{i,t}$. Our

²⁰We examined heterogeneous impacts of recessions across these factors, but we found little evidence of such heterogeneity.

preferred specification 2 (solid blue line) also controls for pre-recession, age group-specific population growth, as described above. Specification 3 (green squares) adds interactions between year indicators and the severity of the previous recession, which is possible for all but the mid-1970s recession. Finally, specification 4 (orange triangles) further includes interactions between year indicators and the severity of *all* previous recessions since the mid-1970s.

Overall, there is little evidence of pre-trends from specification 1. The exceptions are negative pre-trends in the 1980–1982 and 2001 recessions, suggesting that serial correlation from the previous recession or some other factor causing an employment slowdown was already at work before these recessions struck. Adding controls for pre-recession population growth eliminates these pre-trends. Since population growth is calculated over the decade before the recession, it is likely we eliminate secular trends (such as growing migration to certain metros in the South and West).²¹

The recession severity variable s_i is mechanically correlated with a large drop in log employment during the recession. Because we normalize the base period to $t_0 - 2$ (two years before the peak), the coefficient at the trough need not be exactly -1 , although the estimate is generally close to this number, reflecting flat pre-trends.²² Much more interesting is that after each recession, the decline in employment shows little to no recovery over the subsequent 10 years. In the case of the 1990–1991 and 2001 recessions (which have been noted as having “jobless” and “jobloss” national recoveries), employment continued to fall over this period. Moreover, the confidence intervals imply that we can reject a return to initial peak employment in every subsequent time period shown. The graphs also show that the persistent decline in employment is not affected by whether we control for the severity of previous recessions. We obtain similar results when examining employment from County Business Patterns data (Appendix Figure A.2), where we also see a persistent decline in the number of establishments (Appendix Figure A.3).

²¹It is also possible that we remove previous recession-induced changes to population growth. However, the correlations in Table 2 between each of the 1980–1982 and 2001 recessions and their immediately-preceding recessions are small. Since our objective is to estimate the impacts on a local area of a given recession, net of previous ones, whether the pre-trends are driven by secular or long-lasting cyclical effects is not paramount; it is sufficient that we can adequately control for them.

²²The difference between coefficients from peak-to-trough mechanically equals -1 for the log employment regressions because the recession severity variable is constructed as the difference in log employment.

Figure 5 illustrates how the relative effects identified by equation (2) translate into aggregate outcomes. Panel A shows the event study coefficients for the 1980–1982 recession from our preferred specification, and Panel B displays the implied evolution of mean log employment in metro areas with a more versus less severe recession.²³ Employment grows after 1982 in both areas, regardless of recession severity. However, the *level* of employment is persistently lower in areas where the recession was more severe; this is the relative effect identified with cross-sectional variation.

Panel A of Table 4 summarizes the (preferred) specification 2 results seven to nine years after the recession trough.²⁴ The medium-run employment elasticities range from -0.8 to -1.7 . Interestingly, the elasticity is smaller in magnitude—and statistically different—for the two most severe recessions nationwide, which took place from 1980–1982 and 2007–2009. Because recession severity varies both across recessions and across areas within a given recession (Appendix Figure A.1), we also report standardized effects. A one-standard deviation employment decline in the 1973–1975 and 1980–1982 recessions reduced employment by about 7 percent seven to nine years after recession trough. The two most recent recessions exhibit less variation across areas in severity, so the impacts of a one-standard-deviation decline are smaller, although still sizable, between about 3 and 5 percent.

In Figure 6, we examine whether these relative employment losses are broad-based or concentrated in certain industries. For simplicity and ease of presentation, we present estimates for specification 2 only and suppress confidence intervals. We find that, across recessions, the negative impacts are pervasive across sectors, as nearly every point estimate is below zero. Construction and manufacturing experience the largest short-term impacts. Construction recovers somewhat in the earliest two recessions (but little since), and manufacturing—in line with aggregate trends—has

²³We construct these conditional means using estimates of equation (2), holding all covariates besides recession severity at their mean value, and defining the gap between a more and less severe recession as a log employment change difference of -0.12 (equal to the difference in mean recession severity for areas with a log employment change below or above the median).

²⁴We generate the results in this table by restricting the pre-recession coefficients to be zero and pooling the coefficients in equation (2) for post-trough years 1–3, 4–6, 7–9, and (for the first four recessions) 10, in accord with the event study in Figure 4. The coefficient for post-trough years 7–9 summarizes the medium-term impacts while also increasing precision.

recovered partially from the Great Recession (but not so much in earlier recessions). Not surprisingly, government employment tends to show among the smallest declines, although it fared worse during the 1990–1991 and 2007–2009 recessions. The remaining industries tend to move similarly and fall in between, with no clear evidence in any case of an upward slope to suggest an eventual recovery.²⁵ These results show that recessions lead to relative employment declines in many industries.

The consequences of these decreases in employment depend on the degree to which population also responds. We examine this next.

4.2 Population and Migration

In Figure 7 we present estimates of equation (2) where the dependent variable is the log of the total working-age population (15+). For brevity, we show only the results from specification 2, although the patterns are robust to specifications 3 and 4. We see no evidence of pre-trends and find negative, sustained impacts of the recession-induced decline in employment.²⁶ Log population continues to decline long after each recession ends, implying that harder-hit areas remain on a lower population-growth trajectory. The elasticities at recession trough are modest, between -0.2 and -0.3 , but then double or even close to triple over the next decade. The largest effect occurs for the 1990–1991 recession, with a medium-term elasticity of roughly -0.7 , implying that a 10 percent larger decrease in employment during the recession leads to a relative population loss of 7 percent a decade later.

Panel B of Table 4 presents summaries of these results. In terms of standardized effects, the 1980–1982 recession has the largest impact, with a one-standard-deviation decrease in employment during the recession leading to a 4.3 percent reduction in population 7–9 years later. Consistent

²⁵We exclude agriculture and mining, which are small (especially in metro areas) and highly spatially concentrated. We note the unusual positive pattern for utilities and transportation following the Great Recession. The confidence intervals for this series are wider than in previous recessions, and so we are hesitant to read much into these results, but it is possible that recent growth in freight transportation stemming from e-commerce has mitigated employment losses in this sector.

²⁶The lack of pre-trends for the population results is not surprising, as we control for pre-recession population growth.

with the previously-documented decline in migration (Molloy, Smith and Wozniak, 2014; Dao, Furceri and Loungani, 2017), we find that the effects of recessions on population have fallen over time.

We use the SOI data to investigate migration responses more directly for the two most recent recessions. Panels A and B of Figure 8 replicate the event study analysis of population for the 2001 and 2007–2009 recessions using the total number of exemptions in the tax data to proxy for population. The patterns are quite similar to those in Figure 7 and, if anything, the medium-term elasticities are slightly greater in magnitude in the SOI data.

We decompose the net change in population into changes in in-migration, out-migration, and residual net births. This starts with the identity,

$$\text{pop}_{i,t} = \text{pop}_{i,t-1} + \text{inmig}_{i,t} - \text{outmig}_{i,t} + \text{netbirths}_{i,t}, \quad (3)$$

where $\text{inmig}_{i,t}$ is the number of in-migrants between period $t - 1$ and t , $\text{outmig}_{i,t}$ is the number of out-migrants, and $\text{netbirths}_{i,t}$ is the number of births minus deaths. Iterating equation (3) forward and normalizing by a baseline population level, we have

$$\frac{\text{pop}_{i,t}}{\text{pop}_{i,0}} - 1 = \sum_{j=0}^{t-1} \frac{\text{inmig}_{i,j}}{\text{pop}_{i,0}} - \sum_{j=0}^{t-1} \frac{\text{outmig}_{i,j}}{\text{pop}_{i,0}} + \sum_{j=0}^{t-1} \frac{\text{netbirths}_{i,j}}{\text{pop}_{i,0}}. \quad (4)$$

We estimate versions of equation (2), where the dependent variables are each term of the right-hand-side of equation (4). This provides an exact decomposition of the population change.²⁷

Panels C and D present the results of this decomposition analysis. We normalize migration inflows and outflows, as well as residual net births, by the total number of exemptions in year $t_0 - 2$, so the estimates capture changes in rates. By recession trough, in-migration rates have fallen sharply, with a 10 percent decrease in employment during the recession reducing in-migration by about 1 percent of pre-recession population. Over the subsequent decade, these rates recover

²⁷The exact decomposition requires that we include the same covariates in all regressions. We construct net births as a residual using equation (3).

only slightly, and by the end of the horizon they remain between 0.6 and 0.8 percentage points below pre-recession values. Out-migration shows little response until after the recession has ended, although there is a slight upward pre-trend for the 2001 recession. Beginning in the year after the recession trough, however, out-migration rates steadily *decline*, with similar medium-term magnitudes as for in-migration. Net births also show a slight reduction, especially for the Great Recession.

To understand how these components contribute to the change in population, we divide the coefficient estimates in Panels C and D by the respective estimates in Panels A and B. When we also multiply the out-migration estimates by -1 , the sum of the three transformed coefficients— in-migration, out-migration, and net births—sum to 1 and fully decompose the population effects found in the first two panels. These estimates are shown in Panels E and F. The short-term results differ somewhat between the recessions, reflecting the fact that in-migration declines for several years after the 2001 recession trough. However, in both cases we find that lower in-migration accounts for more than 100 percent of the medium-run decrease in population after recessions. Lower out-migration partly offsets falling in-migration, especially for the Great Recession.²⁸

4.3 Employment-to-Population Ratio

After each recession, population declines by less than employment. This implies that employment-to-population ratios also fall after each recession. To examine this local labor market hysteresis more directly, we use the log of the ratio of employment to working-age population as the outcome in Figure 9. These ratios remain lower than their pre-recession peaks, even a decade after recession's end.²⁹

²⁸Monras (2020) also finds this pattern of relative population decline due to falling in-migration for the Great Recession, using variation in recession severity based on pre-recession per capita debt and the share of employment in non-tradeable industries (see also Mian, Rao and Sufi, 2013). His calibrated general equilibrium model predicts that migration dissipates about 60 percent of the long-term impact on wages following the Great Recession.

²⁹The estimates for log employment, log population, and log employment-to-population are approximately, but not exactly, additive due to slightly different controls (in particular, the different lagged dependent variables) included across each specification. We also note that our employment-to-population measure is the ratio of the count of jobs to the number of working-age people; because of multiple job-holding, it is not strictly comparable to official employment-population ratios, which represent the share of the population that is employed.

The elasticities at trough vary somewhat. For the 1973–1975, 1980–1982, and 2001 recessions, these initial elasticities are about -0.75 , but they are slightly larger, closer to -1 , for the 1990–1991 and 2007–2009 recessions. As a consequence of the relatively flat employment trajectories and steady population declines, the employment-to-population trajectories generally show a slight recovery over time, although this is less true for the 1990–1991 and 2001 recessions. The medium-term elasticity remains below -0.3 (and statistically different from 0) in each case, implying a 10 percent decrease in employment during a recession suppresses the employment-to-population ratio a decade later by at least 3 percent, or about 2 percentage points, given a national mean of about 60 percent. Hence, recessions lead to local labor market hysteresis in the form of persistently depressed employment rates.

Panel C of Table 4 reports summaries of these estimates seven to nine years post trough. Whereas a one-standard-deviation employment decline leads to a medium-term reduction in the employment-to-population ratio of about 3–4 percent (1.5–2.5 percentage points) for the four earlier recessions, the relative effect size is only half as large for the Great Recession. Nonetheless, in no case is the population response sufficient to fully counteract employment losses.³⁰

The estimates in Table 4 facilitate a simple decomposition of the post-recession decline in employment, namely that the effect of recession severity on log employment equals the effect on log population plus the effect on the log employment-population ratio. On average, local labor market hysteresis (i.e., the decline in the log employment-population ratio) accounts for about 55 percent of the decline in employment seven to nine years after recession trough, with the remaining 45 percent explained by the decline in population.³¹

³⁰These extensive-margin estimates do not preclude the possibility of impacts at the intensive margin. Census and ACS microdata reveal declines in full-year and full-time, full-year employment rates, with somewhat imprecise but larger magnitudes for these outcomes than for overall employment rates.

³¹The equally-weighted average coefficient in Table 4 is -1.23 for log employment and -0.55 for log population, so the recession-induced decrease in population explains 45 percent ($=0.55/1.23$) of the decline in employment.

4.4 Earnings per capita

The damaging effects of local recessions need not manifest only through extensive-margin employment losses; they may also affect wages, hours worked, and other dimensions of job quality. We thus next examine the summary measure of annual earnings per capita (which encapsulates both the quantity and quality of employment).

Figure 10 shows estimates of equation (2) for the log of real earnings per capita, where we use the PCE deflator to adjust for inflation. There is again evidence of local labor market hysteresis, with per-capita earnings below their pre-recession peak for each recession over the entire horizon. Trough elasticities are typically between -0.5 and -0.75 , though slightly larger for the 2007–2009 recession. As with employment rates, there is evidence of partial recovery following the 1973–1975, 1980–1982, and 2007–2009 recessions, but not after the 1990–1991 or 2001 episodes. Panel D of Table 4 shows that a one-standard-deviation greater employment decline results in earnings per capita between 2 percent (Great Recession) to 4 percent (2001 recession) lower than they otherwise would have been nearly a decade later.

We use the Census/ACS to examine distributional impacts on the earnings of prime-age workers. Specifically, we estimate a variant of equation (2) in which dependent variables are drawn from the Census or 3-year ACS period following the recession.³² We look at the mean and the 10th, 50th, and 90th percentiles of the log annual earnings distribution. The first row of Panel A of Table 5 shows that estimates for mean log earnings are generally similar to those from the BEAR data presented above, although magnitudes are somewhat smaller, especially for the 1990–1991 recession. The percentile estimates in the next three rows, moreover, indicate that recessions generally decrease earnings throughout the distribution. Longer-term earnings impacts tend to be

³²We use the 1980 Census for the 1973–1975 recession, the 1990 Census for the 1980–1982 recession, the 2000 Census for the 1990–1991 recession, the 2005–2007 ACS for the 2001 recession, and the 2015–2017 ACS for the 2007–2009 recession. Because the variables used are based on the previous calendar year (Census) or preceding 12 months (ACS), these outcomes are generally measured before subsequent recessions begin. In these regressions, we control for lagged dependent variables in 1970 for the recession in 1973–1975, in 1970 and 1980 for the one in 1980–1982, in 1980 and 1990 for the one in 1990–1991, in 1990 and 2000 for the one 2001, and in 2000 and 2005–2007 for the one in 2007–2009. These controls generally capture the pre-recession period, again because outcomes are based on the previous calendar year or 12 months.

less severe at the top of the distribution; for the middle three recessions, the brunt is borne at the bottom, although impacts at the middle are more severe for the 1973–1975 and 2007–2009 recessions. These results are consistent with the finding that job losses are more concentrated among lower parts of the earnings distribution (Hoynes, Miller and Schaller, 2012), but we find that medium-term impacts have reached farther up the distribution more recently.

These earnings declines could stem from a reduction in hours worked, a reduction in earnings per hour, or both. Thus, in Appendix Table A.1 we show additional Census/ACS estimates for (mean) log weekly and log hourly earnings (with those for log annual earnings repeated from Table 5 for convenience). If the earnings losses are driven by a reduction in hours, hourly wages could be relatively unaffected several years later. On the other hand, if the recession slows wage growth or displaced workers are less likely to find good employer matches (Lachowska, Mas and Woodbury, 2020), hourly wage losses may explain more of the annual earnings declines. The results indicate that the latter story better fits the data, as the estimated effects on log hourly wages are at least two-thirds, and generally closer to four-fifths, of those for log annual wages. Decreases in work attachment at the intensive margin therefore explain relatively little of the persistent reduction of annual earnings per capita.

4.5 Long-Run Results

Our main results focus on a ten-year post-recession window. There is evidence of a partial recovery in employment-population ratios for the 1973–1975, 1980–1982, and 2007–2009 recessions, so a natural question is whether local areas eventually recovered. Appendix Figures A.4 and A.5 show that employment and employment-population ratios had not recovered by 2017 for any recession. The partial recovery from the 1973–1975 recession reversed itself in the mid-1980s, after which employment rates declined for the next 20 years. A similar pattern exists for the 1980–1982 recession: starting in the mid-1990s, the partial recovery reverses itself and employment rates fall for several decades. The declines in employment rates following the 1990–1991 and 2001 recessions were extremely stable over time. In sum, local labor market hysteresis persists for several decades

after each recession.

Moreover, there is little evidence that the persistent decline in local economic activity is driven by subsequent, *independent* shocks that occur after recessions. Instead, our results indicate that local economic activity tends to evolve smoothly after recessions.³³ If areas faced a severe recession and then an independent shock a few years later, we would expect to see post-recession years with sharp decreases in employment, which are not evident in Figure 4 or Appendix Figure A.4.

4.6 Robustness

Our results are robust to different measures of recession severity and different definitions of local labor markets. In particular, Appendix B.1 shows that our results are very similar when using private wage and salary employment from BEAR or QCEW data to measure recession severity. Appendix B.2 discusses results when replacing the log employment change with the log employment change predicted by an area's industry mix (Bartik, 1991). While there are several reasons to prefer the log employment change over the predicted log employment change, the results are generally similar. Finally, Appendix B.3 shows that our results are nearly identical when examining commuting zones instead of metropolitan areas.

5 The Role of Composition Changes

One explanation for why recessions lead to persistent declines in the employment-population ratio and earnings per capita is a change in worker composition due to differential migration responses. We next examine these composition changes and explore whether they explain local labor market hysteresis. While we find some evidence of composition changes, the qualitative and quantitative pattern of results suggests that composition changes are not the key mechanism. Instead, local labor market hysteresis appears to stem mainly from lasting impacts on individuals, consistent with evidence on the effects of job displacement (e.g., Jacobson, LaLonde and Sullivan, 1993;

³³The exception is that areas hit harder by the 1973–1975 recession were also hit harder by the Great Recession, 35 years later (consistent with the correlations in Table 2).

Lachowska, Mas and Woodbury, 2020) and the Great Recession (Yagan, 2019).

5.1 Examining Composition Changes

First, we use equation (2) to directly estimate the effects of recessions on the composition of individuals in a metro area. We focus on age, education, and occupation, as these directly relate to an area's earnings capacity. Figure 11 plots the effects of recession severity on the share of population ages 0–14, 15–39, 40–64, and 65 and above.³⁴ Across all recessions, we see a persistent increase in the share age 65 and above, alongside a decrease in the share age 15–39. This is consistent with the fact that early career workers are more mobile than older individuals (e.g., Molloy, Smith and Wozniak, 2011). The response of other age groups varies more: the 0–14 share declines following the 1973–1975, 1980–1982, and 2007–09 recessions, but rises after 1990–1991 and does not change after the 2001 recession. The 40–64 share generally increases, with the exception of 1990–1991. Most of these point estimates are statistically significant (filled-in markers indicate significance at the five-percent level). They imply that a one-standard-deviation increase in recession severity leads to a medium-term 0.2–0.6 percentage point (0.5–1.6 percent) decrease in the 15–39 share and a 0.1–0.6 percentage point (0.8–5.0 percent) increase in the share age 65 and above (see Appendix Table A.4).

Table 6 reports estimates of recession severity on occupational structure and educational composition, using decennial Census and ACS data. Panel A examines the share of employed individuals age 25–54 in three occupation groups: managerial, professional, and technical; administrative, office, production, and sales; and manual and service. We follow Autor (2019) in using these classifications, which correspond to high-, medium-, and low-paid occupations. The 1973–1975, 1990–1991, and 2007–2009 recessions decreased the share of workers in managerial, professional, and technical jobs, while increasing the share in manual and service occupations. There is less evidence of an impact on occupational structure following the 1980–1982 and 2001 recessions. Panel B examines the share of individuals age 25–54 with a high school degree or less, some college (but

³⁴In the age, education, and occupation composition regressions, we include the same explanatory variables in all regressions to ensure that the coefficients add up to zero across groups.

less than a four-year degree), and a four-year degree or more. The results mirror those in Panel A: the 1973–1975, 1990–1991, and 2007–2009 recessions increased the share of individuals with a high school degree or less and decreased the college share. The coefficients for the Great Recession imply that a one-standard-deviation decline in employment decreases the share of workers employed in managerial, professional, and technical occupations by 0.4 percentage points (1 percent). The same employment change also increases the share of individuals with no more than a high school degree by 0.8 percentage points (2 percent) and decreases the share of individuals with a bachelor’s degree by 0.6 percentage points (2 percent).

In sum, all recessions led to a modest shift in the population age distribution away from early career workers and towards the elderly. Some recessions decreased the share of workers employed in high-wage occupations, and the same recessions decreased the share of residents with a college degree. The changes in age, occupation, and education are modest in size, which suggests that these composition shifts likely cannot explain all of the persistent impacts on local labor markets. Furthermore, the fact that we find local hysteresis even in recessions for which education and occupation are stable suggests that composition shifts along these dimensions are not driving the persistent effects of recessions on local areas.

5.2 Composition-Adjusted Impacts on Earnings

To more directly quantify the role of composition changes, we estimate the effects of recessions on residualized earnings. We regress log annual earnings of prime-age workers from the Census and ACS against indicators for education (of which there are 11), age (30), sex (2), and race/ethnicity (4), plus interactions between the education indicators and a quartic in age. We estimate these regressions separately for each year and use metro-area averages and percentiles of the residuals as dependent variables in our regressions.

Panel B of Table 5 presents results for composition-adjusted wage and salary earnings (Panel A, already discussed, shows non-adjusted results). The composition-adjusted results tend to be somewhat smaller in magnitude, which indicates that the age and education shifts identified above

partly contribute to the persistent decline in earnings. At the same time, the composition-adjusted impacts remain sizable, and for the 2001 recession, they actually increase in magnitude. Overall, composition changes along observed dimensions explain less than half of the overall effects of recessions on mean earnings.

6 A Comparison to Results from the Blanchard and Katz (1992) Model

The widespread evidence of local labor market hysteresis that we present above differs from the well-known results of Blanchard and Katz (1992)—hereafter BK—who find that the unemployment rate, labor force participation rate, and wages return to trend within ten years after state-level employment declines. At a basic level, our empirical strategy is similar to BK, in that we both rely on cross-sectional variation in how local areas respond to employment changes. The key difference is that BK estimate vector autoregressions (VARs) while we estimate event study models. Other research on local labor market outcomes has also used VARS. Dao, Furceri and Loungani (2017), for example, use a different source of identification in their VARs and find a similar degree of convergence, although population is less responsive in their short-run results. Moreover, Yagan (2019) shows that the BK model implies complete recovery of the employment-population ratio within eight years following the 1980–1982 and 1990–1991 recessions, and slower but steady convergence following the 2007–2009 recession. This section explores why our results differ. We show that finite sample bias, stemming from the relatively short time-series that researchers must rely on, leads to spurious recovery of impulse response functions in the BK VAR.

To facilitate discussion, we first introduce the BK VAR. The key variables are the annual change in log employment, $\Delta e_{i,t}$, the level of the log employment-labor force ratio, $el_{i,t}$, and the level of the log labor force-working age population ratio, $lp_{i,t}$. BK account for aggregate trends by differencing out the same variables for the aggregate U.S. economy. They estimate the following

recursive VAR using data from 1976–1990:

$$\Delta e_{i,t} = \alpha_{i10} + \alpha_{11}(L)\Delta e_{i,t-1} + \alpha_{12}(L)el_{i,t-1} + \alpha_{13}(L)lp_{i,t-1} + \epsilon_{i,e,t}, \quad (5)$$

$$el_{i,t} = \alpha_{i20} + \alpha_{21}(L)\Delta e_{i,t} + \alpha_{22}(L)el_{i,t-1} + \alpha_{23}(L)lp_{i,t-1} + \epsilon_{i,el,t}, \quad (6)$$

$$lp_{i,t} = \alpha_{i30} + \alpha_{31}(L)\Delta e_{i,t} + \alpha_{32}(L)el_{i,t-1} + \alpha_{33}(L)lp_{i,t-1} + \epsilon_{i,lp,t}. \quad (7)$$

BK include two lags of each explanatory variable, along with state fixed effects α_{i10} , α_{i20} , and α_{i30} . After estimating these equations (which can be done using three separate OLS regressions), BK construct the impulse response functions (IRFs) of each variable with respect to a one percent decrease in employment (i.e., a reduction in $\epsilon_{i,e,t}$ of 0.01).³⁵ Primary interest lies in these IRFs, which are constructed using only the coefficients in equations (5)–(7).

Figure 12 shows IRFs of log employment, the “unemployment rate” (one minus the log employment-labor force ratio), and the log participation rate. We use BLS LAUS data from 1976–1990 to generate these results, which are extremely similar to Figure 7 of BK. Notably, the unemployment rate and participation rate completely recover within eight years.

Our preferred unit of geography is a metropolitan area or commuting zone. When using sub-state areas, reliable data on labor force participation are available for a limited time period at best.³⁶ Consequently, the most comparable outcome is the employment-population ratio. The IRF of the log employment-population ratio can be constructed as the sum of the IRFs of the log employment-labor force ratio and the log labor force-population ratio. Panel B of Figure 12 shows this IRF from the BK model. As expected given the results in Panel A, the IRF shows complete recovery of the employment rate.

To facilitate the analysis below, we simplify the BK model in two ways. First, we estimate a two-equation VAR in first differences of log employment and levels of the log employment-

³⁵Because this is a recursive VAR, there is a natural unit of measurement for $\epsilon_{i,e,t}$. In contrast, a structural VAR does not feature this property (See, e.g., Stock and Watson, 2001).

³⁶The BLS provides county-level labor force estimates from 1990 onward. A separate series contains county-level labor force estimates from 1976–1989, but BLS stresses that this series is not comparable to the 1990-forward series. Both data sets rely substantially on extrapolations from statistical models, as household surveys are not large enough to reliably measure unemployment and labor force for most counties.

population ratio, $ep_{i,t}$. Second, we include only one lag of each variable. The resulting recursive VAR is:

$$\Delta e_{i,t} = \tilde{\alpha}_{i10} + \tilde{\alpha}_{11}\Delta e_{i,t-1} + \tilde{\alpha}_{12}ep_{i,t-1} + \tilde{\epsilon}_{i,e,t}, \quad (8)$$

$$ep_{i,t} = \tilde{\alpha}_{i20} + \tilde{\alpha}_{21}\Delta e_{i,t} + \tilde{\alpha}_{22}ep_{i,t-1} + \tilde{\epsilon}_{i,ep,t}. \quad (9)$$

These simplifying assumptions have little impact on the estimated IRF of the log employment-population ratio, as shown in Panel B of Figure 12.

Equations (8) and (9) facilitate simpler expressions of the IRF in terms of the underlying parameters. Consider a one-time change in log employment in period t through $\tilde{\epsilon}_{i,e,t}$. The subsequent impacts on the log employment-population ratio are:

$$\frac{dep_{i,t}}{d\tilde{\epsilon}_{i,e,t}} = \tilde{\alpha}_{21}, \quad (10)$$

$$\frac{dep_{i,t+1}}{d\tilde{\epsilon}_{i,e,t}} = \tilde{\alpha}_{21}^2\tilde{\alpha}_{12} + \tilde{\alpha}_{21}\tilde{\alpha}_{11} + \tilde{\alpha}_{21}\tilde{\alpha}_{22}, \quad (11)$$

$$\frac{dep_{i,t+2}}{d\tilde{\epsilon}_{i,e,t}} = \tilde{\alpha}_{21}^3\tilde{\alpha}_{12}^2 + 2\tilde{\alpha}_{21}^2\tilde{\alpha}_{11}\tilde{\alpha}_{12} + 2\tilde{\alpha}_{21}^2\tilde{\alpha}_{22}\tilde{\alpha}_{12} + \tilde{\alpha}_{21}\tilde{\alpha}_{11}^2 + \tilde{\alpha}_{21}\tilde{\alpha}_{22}^2 + \tilde{\alpha}_{21}\tilde{\alpha}_{11}\tilde{\alpha}_{22}. \quad (12)$$

Similar expressions exist for the IRF at later horizons, but these first few periods are adequate to highlight some important takeaways. First, bias in the OLS estimates of equations (8) and (9) can generate bias in the IRF, because the IRF is a function of the coefficients in these equations. Second, bias in the IRF can be a nonlinear function of bias in the coefficients, because the IRF is a nonlinear function of these coefficients. Third, bias in the IRF can increase in importance over time. For example, if the OLS estimates are attenuated, this bias generates an IRF that can converge towards zero even if the true IRF does not. This arises because the exponents in the IRF increase with time, magnifying attenuation bias.³⁷

The potential for finite sample attenuation bias in autoregressive models, including VARs, has long been recognized (e.g., Hurwicz, 1950; Shaman and Stine, 1988; Stine and Shaman, 1989;

³⁷More generally, if $a \in (0, 1)$ is an attenuation factor, then $(ax)^t$ converges to zero faster than x^t .

Pope, 1990; Kilian, 1998, 1999; Kilian and Lütkepohl, 2017).³⁸ This bias arises because residuals are not independent of all regressors in an autoregression, since regressors are lagged dependent variables.

To explore this issue further, we conduct a Monte Carlo study of finite sample bias in empirically relevant scenarios. We assume that log employment is a random walk:

$$e_{i,t} = e_{i,t-1} + \varepsilon_{i,e,t}, \quad (13)$$

and that log population depends on changes in log employment as follows:

$$p_{i,t} = p_{i,t-1} + (1 - \phi)\Delta e_{i,t} + \varepsilon_{i,p,t}. \quad (14)$$

This implies that the log employment-population ratio is:

$$ep_{i,t} = ep_{i,t-1} + \phi\Delta e_{i,t} - \varepsilon_{i,p,t}. \quad (15)$$

In terms of equations (8) and (9), this data generating process (DGP) sets $\tilde{\alpha}_{i10} = \tilde{\alpha}_{i20} = 0$ (state fixed effects do not matter), $\tilde{\alpha}_{11} = \tilde{\alpha}_{12} = 0$ (log employment is a random walk), $\tilde{\alpha}_{21} = \phi$, and $\tilde{\alpha}_{22} = 1$. Changes in log employment have a permanent effect on the log employment-population ratio, with the true IRF equal to ϕ at all horizons. We study DGPs with this feature to examine whether the BK VAR accurately estimates persistent effects of declines in local area employment in finite samples.

We calibrate the DGP using state-level LAUS data. We assume that all variables are distributed normally. The first period mean and variance of $e_{i,t}$ and $p_{i,t}$ equal those observed in the 1976 LAUS data, and the variances of $\varepsilon_{i,e,t}$ and $\varepsilon_{i,p,t}$ approximate the variance of log employment and

³⁸Kilian (1998, 1999) specifically address bias in impulse responses. The methods discussed in these papers allow for bias-corrected confidence intervals of impulse responses, but we focus on point estimates here for simplicity. In general, “there is no consensus in the literature that impulse responses should be estimated based on bias-adjusted slope parameters rather than the original [least squares] estimates” (Kilian and Lütkepohl, 2017, p. 37).

population in subsequent years.³⁹ We focus on the case where $\phi = 0.75$, with 50 cross-sectional observations and different time-series lengths, T .

Panel A of Figure 13 plots the true IRF along with average estimates across 499 Monte Carlo simulations. The true IRF reveals a persistent decrease in the employment-population ratio. For $T = 15$, which is approximately the number of years available to BK when they wrote their paper, finite sample bias leads to rapid recovery of the employment-population ratio. Ten years after the shock, the IRF estimate is downward-biased by 89 percent. This bias remains very large for $T = 25$ and $T = 50$. Because previous work on local labor market hysteresis uses annual data, the relevant values of T range from 15 to 50. The bias remains sizable for $T = 100$, for which the bias ten years after the shock equals 25 percent. Even for $T = 500$, finite sample bias incorrectly implies slow, but steady recovery.⁴⁰ The bias stems from an insufficient number of time series observations, so instrumental variables do not solve this problem in general. Not surprisingly, we find a sufficiently strong instrumental variable (as has been used in previous work) generates nearly identical results in our DGP (in which an instrument is not needed to obtain consistent estimates).

Event study estimates do not suffer from finite sample bias due to small T in this setting. To show this, we use the same DGP and estimate the following event study regression:

$$ep_{i,t} = \Delta e_i \delta_t + \beta_t + ep_{i,-3} \gamma_t + \varepsilon_{it}, \quad (16)$$

where the shock Δe_i occurs between year 0 and 1, and, to be consistent with the VAR IRFs, we normalize the coefficient $\delta_0 = 0$. This is the direct analog of equation (2). Under this DGP, we have $\delta_t = -0.75$ for all years $t \geq 1$. Hence, the event study coefficient δ_t (which is akin to an empirical impulse response function) and the IRF coincide in population for all post-shock years. Panel B of Figure 13 shows that there is no systematic bias in estimates of δ_t , regardless of T .

In sum, finite sample bias can lead the BK VAR to find evidence of recovery when there is

³⁹In particular we set $e_{i,0} \sim \mathcal{N}(13.94, 1.00^2)$, $p_{i,0} \sim \mathcal{N}(14.49, 1.02^2)$, $\varepsilon_{i,e,t} \sim \mathcal{N}(0, 0.015^2)$, and $\varepsilon_{i,p,t} \sim \mathcal{N}(0, 0.015^2)$.

⁴⁰Appendix Table A.5 reports the underlying bias in estimates of the parameters of equations (8) and (9) for various values of T . All parameters are biased. While this bias is modest in many cases, it is amplified in the IRF. The IRF bias is of primary interest, because the IRF is used to quantify the extent of hysteresis.

none. The event study regressions that we estimate are not subject to this finite sample bias in empirically relevant DGPs. We believe that finite sample bias is the main explanation for why we find widespread evidence of local hysteresis, while papers estimating the BK VAR do not.⁴¹ To be clear, we do not claim that all VARs are incapable of identifying persistent effects. However, finite bias is evident in DGPs that are relevant for VARs estimated in previous work on local labor market hysteresis (Blanchard and Katz, 1992; Dao, Furceri and Loungani, 2017; Yagan, 2019).

7 Conclusion

This paper examines the effects of recessions on U.S. local labor markets. Studying five recessions over the course of 50 years, we find that employment losses which emerge during recessions are long-lasting, implying a persistent relative decline in local labor demand. Population falls during recessions and for several years afterwards, but by less than employment. Most importantly, recessions lead to local labor market hysteresis: persistent declines in employment-to-population ratios and earnings per capita for over a decade after recession's end. Recessions change the composition of an area's residents, most notably leading to an increase in the share of the population over age 64 and a decrease in the share age 15–39, but composition changes are not the key driver of local labor market hysteresis.

In short, recessions produce enduring economic disruptions to local labor markets, and this pattern has existed for at least the past five decades. While there are some differences across recessions, more striking is the similarity of the effects, especially in light of different macroeconomic drivers and secular changes in the economy over time. One explanation for why these results have not been shown before is that an influential approach in the literature—estimating vector autoregressions and calculating impulse response functions as in Blanchard and Katz (1992)—incorrectly finds convergence after a persistent decline in local labor demand because of finite sample bias. In contrast, the event study models that we estimate do not suffer from this bias.

⁴¹The literature estimating BK VARs uses state-level data. Estimating our event study models on state-level data also yields widespread hysteresis, so this does not explain the difference.

Cross-sectional variation in recession severity allows us to estimate relative effects by comparing local labor markets that experience a more versus less severe recession. This variation, however, does not allow us to identify the absolute effects of recessions on local economic activity (e.g., Nakamura and Steinsson, 2014). Nonetheless, local labor market hysteresis raises the concern that the capabilities of workers in some areas remain underutilized. This “direct effect” could lower aggregate output. At the same time, there could be an offsetting indirect effect if recessions reallocate employment to more productive areas. We examine this possibility through simple back-of-the-envelope calculations, described in Appendix B.4, and find no evidence of such productivity-enhancing reallocation. Fully assessing the impacts of local labor market hysteresis on aggregate output requires additional assumptions about the counterfactual evolution of economic activity in the absence of recessions, which we leave for future work.

Irrespective of the aggregate consequences of local labor market hysteresis, our findings have important implications for labor market dynamism, the economic opportunities of workers and their children, and optimal policy responses. Our results show that recessions lead to a sizable reallocation of employment across space. At the same time, we find that recessions reduce both in-migration and out-migration in severely impacted areas, which indicates limited ability or willingness of households to move across areas to equilibrate shifts in labor demand. Moreover, the persistent decrease in local economic activity limits the opportunities available to both adults and children in these places. For workers, most of the decrease in earnings is due to a decrease in hourly wages, which indicates that offsetting these long-run effects might require investments in human capital, labor demand, or both. For children, the long-run decline in local economic activity likely reduces their economic mobility (Stuart, 2018). The vast majority of policy responses to recessions focus on short-term conditions. Our results imply that additional consideration should be paid to recessions’ long-term effects.

A final important consideration is that this study focuses on the United States. Differences across countries in labor market institutions and other policies could influence the degree of local hysteresis. Future work on how recessions affect local labor markets in other countries will en-

hance our understanding of labor market dynamics and provide valuable lessons for optimal—and possibly heterogeneous—policy responses.

Wholesale Trade	0.039	−0.027	−169,900	0.037	−0.070	−443,300			
Mining	0.005	−0.012	−9,000	0.006	0.107	114,300			
Agriculture, Forestry, Fisheries	0.005	−0.010	−8,700	0.005	−0.017	−14,200			

Notes: Table reports nationwide wage and salary employment changes during recessions. Employment changes are from 1973–1975, 1979–1982, 1989–1991, 2000–2002, and 2007–2009. The 1973–1991 data are based on SIC industries, and the 2000–2009 data are based on NAICS industries. Industry changes may not sum to total changes due to rounding.

Source: Authors' calculations using Bureau of Economic Analysis Regional Economic Accounts (BEAR) data.

Table 2: Correlation of Metropolitan Area Recession Severity

	Change in Log Employment During Recession Years				
	1973–75	1979–82	1989–91	2000–02	2007–09
Panel A: Unadjusted					
1973–75	1.000				
1980–82	0.386	1.000			
1989–91	0.462	0.156	1.000		
2000–02	0.442	0.412	0.280	1.000	
2007–09	0.346	0.206	–0.008	0.154	1.000
Panel B: Adjusted for Census division					
1973–75	1.000				
1980–82	0.326	1.000			
1989–91	0.291	0.174	1.000		
2000–02	0.290	0.308	0.236	1.000	
2007–09	0.354	0.064	–0.054	0.089	1.000
Panel C: Adjusted for Census division and pre-recession population growth					
1973–75	1.000				
1980–82	0.259	1.000			
1990–91	0.167	0.017	1.000		
2001	0.140	0.082	0.100	1.000	
2007–09	0.392	0.276	0.047	0.210	1.000

Notes: Table reports correlations of log wage and salary employment changes across recessions for 363 metropolitan areas. Panel B reports correlations after partialling out Census division fixed effects, and Panel C partials out Census division fixed effects and pre-recession population growth.

Source: Authors' calculations using BEAR data.

Table 3: Characteristics of Metro Areas with More versus Less Severe Recessions

	Recession									
	1973–75		1980–82		1990–91		2001		2007–09	
	Less Severe	More Severe								
Population (000s)	328.6	589.4	545.1	426.3	325.9	760.2	524.3	725.3	609.0	738.7
Log pop. growth	0.090	0.067	0.247	0.108	0.136	0.079	0.162	0.096	0.091	0.117
Employment rate	0.517	0.537	0.532	0.547	0.545	0.579	0.590	0.632	0.611	0.583
Manufacturing share	0.141	0.253	0.140	0.236	0.132	0.178	0.095	0.163	0.081	0.110
Real earnings per capita (000s)	25.4	25.2	27.4	27.3	30.8	32.4	37.9	39.4	41.4	42.2
HS degree+ share	0.559	0.505	0.676	0.655	0.763	0.746	0.808	0.814	0.855	0.847
BA+ share	0.119	0.096	0.172	0.141	0.194	0.182	0.229	0.219	0.259	0.240
Nonwhite share	0.146	0.134	0.210	0.121	0.189	0.188	0.257	0.203	0.275	0.275
Foreign-born share	0.028	0.027	0.048	0.028	0.045	0.043	0.081	0.047	0.068	0.080

Notes: Population, employment rate, manufacturing share of employment, and real earnings per capita are measured two years before the recession start year. The last four rows are measured as of the closest decennial census to the recession start year, except for the 2007–2009 recession, which is measured from the 2005–2009 ACS. Population growth is from 1969 to 1973 for the 1973–1975 recession and over the previous ten years for the other recessions. We denote an area as suffering a more severe recession if its log employment change for a given recession is less than the median across CBSAs for that recession.

Source: Authors' calculations of data from BEAR, decennial Censuses and American Community Surveys (via IPUMS and NHGIS), and Surveillance, Epidemiology, and End Results (SEER).

Table 4: Summary of Impacts of Log Employment Decreases During Recessions on Metropolitan Area Economic Activity

	Recession				
	1973–75	1980–82	1990–91	2001	2007–09
Panel A: Dependent Variable: Log Employment					
Coefficient, 7–9 years after trough	–1.294 (0.184)	–0.871 (0.138)	–1.656 (0.153)	–1.543 (0.131)	–0.790 (0.123)
Implied effect of 1 SD log employment decrease	–0.072	–0.069	–0.075	–0.053	–0.031
Panel B: Dependent Variable: Log Population Age 15+					
Coefficient, 7–9 years after trough	–0.648 (0.113)	–0.557 (0.078)	–0.627 (0.127)	–0.548 (0.099)	–0.371 (0.061)
Implied effect of 1 SD log employment decrease	–0.036	–0.044	–0.029	–0.019	–0.014
Panel C: Dependent Variable: Log Employment-Population Ratio					
Coefficient, 7–9 years after trough	–0.600 (0.100)	–0.360 (0.101)	–0.924 (0.123)	–0.992 (0.133)	–0.424 (0.101)
Implied effect of 1 SD log employment decrease	–0.033	–0.028	–0.042	–0.034	–0.017
Panel D: Dependent Variable: Log Earnings per Capita					
Coefficient, 7–9 years after trough	–0.407 (0.074)	–0.389 (0.094)	–0.699 (0.116)	–1.182 (0.183)	–0.477 (0.139)
Implied effect of 1 SD log employment decrease	–0.023	–0.031	–0.032	–0.040	–0.019
SD of log employment change	0.056	0.079	0.045	0.034	0.039

Notes: Table reports estimates of equation (2), separately for each recession. We impose the constraint that pre-recession coefficients equal zero and group post-recession coefficients across years 1–3, 4–6, 7–9, and (for the earliest four recessions) 10. Dependent variables are indicated in the panel titles, and the key independent variable is the change in log wage and salary employment during the recession from BEAR data. All regressions control for division-year fixed effects and interactions between pre-recession population growth and year indicators. There are 363 metropolitan areas in the sample. Standard errors are clustered by metropolitan area.

Source: Authors' calculations using BEAR and SEER data.

Table 5: Impacts of Log Employment Decreases During Recessions on Metropolitan Area Annual Wage Earnings, Census/ACS

	Recession				
	1973–75	1980–82	1990–91	2001	2007–09
Panel A: Without Composition Adjustment					
Average log earnings	−0.203 (0.095)	−0.506 (0.092)	−0.124 (0.101)	−0.547 (0.104)	−0.549 (0.127)
10th percentile, log earnings	−0.024 (0.168)	−0.696 (0.161)	−0.165 (0.169)	−0.760 (0.247)	−0.339 (0.230)
50th percentile, log earnings	−0.212 (0.105)	−0.477 (0.091)	0.009 (0.083)	−0.375 (0.098)	−0.677 (0.127)
90th percentile, log earnings	−0.103 (0.085)	−0.292 (0.065)	−0.058 (0.089)	−0.371 (0.093)	−0.441 (0.145)
Panel B: With Composition Adjustment					
Average log earnings	−0.155 (0.086)	−0.333 (0.076)	−0.056 (0.081)	−0.627 (0.090)	−0.359 (0.112)
10th percentile, log earnings	−0.023 (0.160)	−0.444 (0.153)	−0.065 (0.129)	−1.082 (0.243)	−0.267 (0.219)
50th percentile, log earnings	−0.190 (0.077)	−0.314 (0.071)	−0.021 (0.075)	−0.490 (0.070)	−0.358 (0.093)
90th percentile, log earnings	−0.125 (0.083)	−0.216 (0.048)	−0.053 (0.059)	−0.437 (0.081)	−0.294 (0.125)

Notes: Table reports estimates of separate regressions for each recession. The dependent variable is indicated in the row titles and taken from the post-recession Census year (1980, 1990, 2000, 2005–2007, and 2015–17, respectively). The key independent variable is the change in log wage and salary employment during the recession from BEAR data. The 1973–75 regression controls for the 1970 value of the dependent variable, and other regressions control for two lagged/contemporaneous values. Sample limited to individuals age 25–54. All regressions control for division-year fixed effects and interactions between pre-recession population growth and year indicators. The dependent variables in Panel B are constructed using residuals from regressing log earnings on indicators for education, indicators for age, an indicator for sex, and indicator for race/ethnicity (white/black/Hispanic/other), plus interactions between the education indicators and a quartic in age. Standard errors are robust to heteroskedasticity.

Table 6: Impacts of Log Employment Decreases During Recessions on Metropolitan Area Occupational Structure and Education Composition

	Recession				
	1973–75	1980–82	1990–91	2001	2007–09
Panel A: Share of Employed Workers by Occupation Group					
Managerial, professional, technical	–0.106 (0.033)	–0.025 (0.028)	–0.061 (0.031)	0.002 (0.036)	–0.093 (0.040)
Administrative, office, production, sales	–0.054 (0.028)	–0.001 (0.021)	–0.045 (0.027)	–0.010 (0.032)	0.014 (0.034)
Manual and service	0.160 (0.038)	0.026 (0.033)	0.107 (0.033)	0.008 (0.038)	0.079 (0.045)
Panel B: Share of Individuals by Educational Attainment					
High school degree or less	0.130 (0.052)	0.001 (0.040)	0.110 (0.043)	0.037 (0.038)	0.209 (0.044)
Some college	–0.028 (0.027)	0.028 (0.024)	–0.060 (0.030)	0.001 (0.032)	–0.064 (0.033)
Four-year degree or more	–0.103 (0.038)	–0.029 (0.026)	–0.050 (0.032)	–0.038 (0.030)	–0.145 (0.040)

Notes: Table reports estimates of separate regressions for each recession. The dependent variable is indicated in the row titles. The key independent variable is the change in log wage and salary employment during the recession from BEAR data. We control for all occupation or education shares (which are mutually exclusive). Sample limited to individuals age 25–54. See notes to Table 5.

Source: Authors' calculations using BEAR, decennial Census, and ACS data.

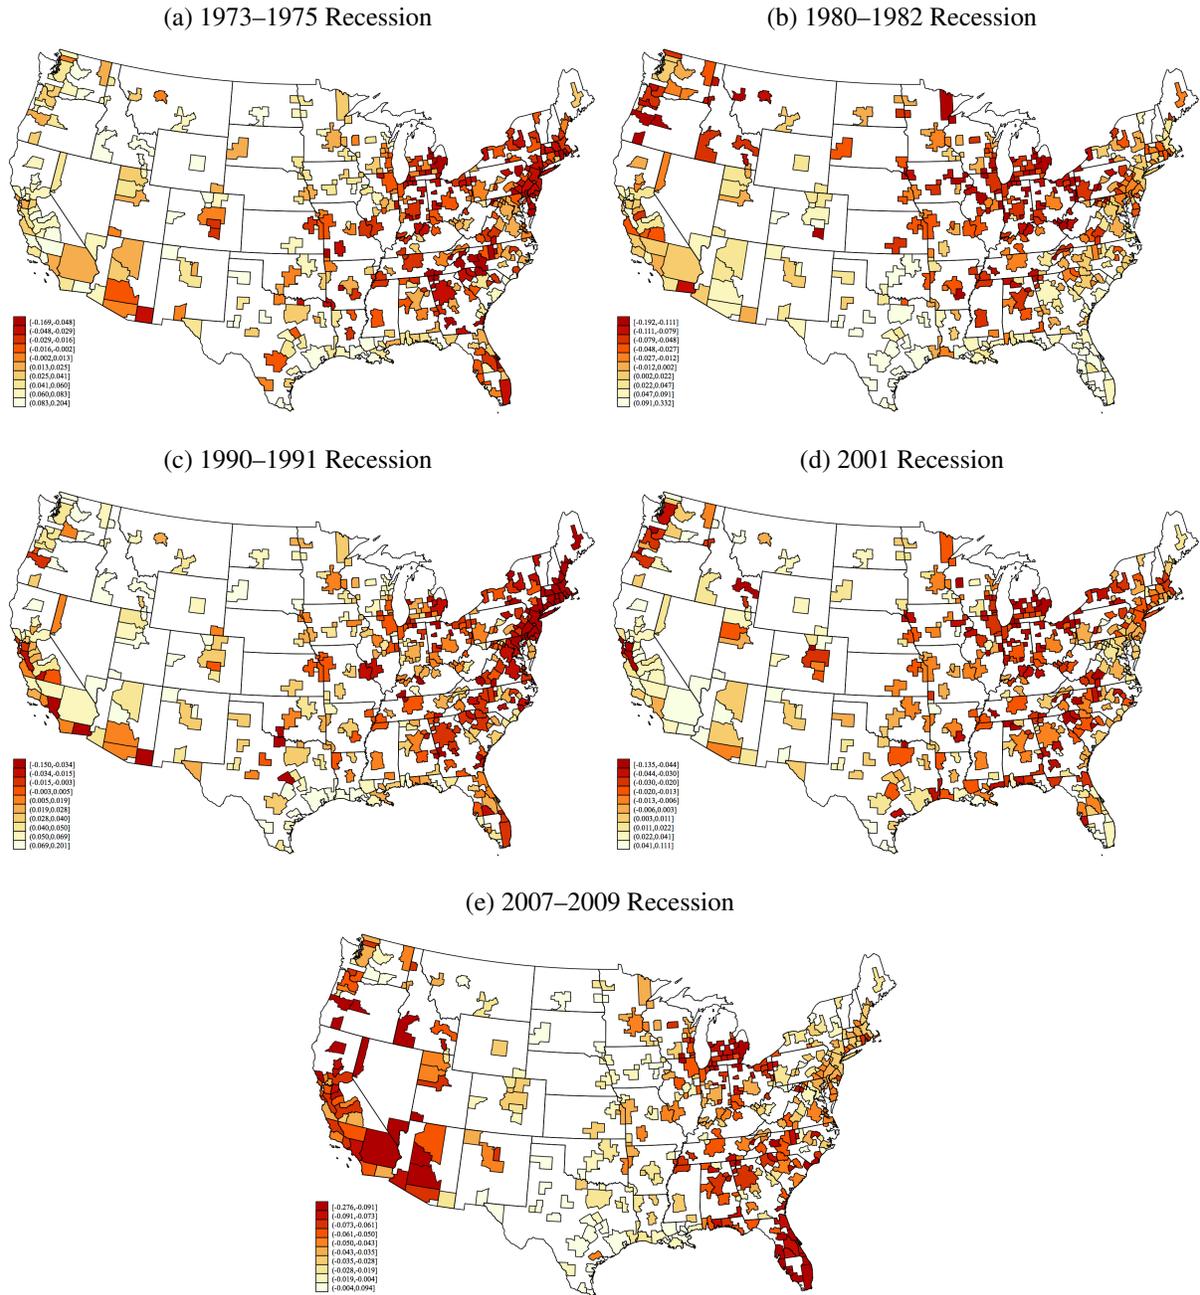

Figure 1: Aggregate Employment and Recessions, 1969–2017

Notes: Figure shows seasonally adjusted national nonfarm employment. The shading indicates NBER national recession dates.

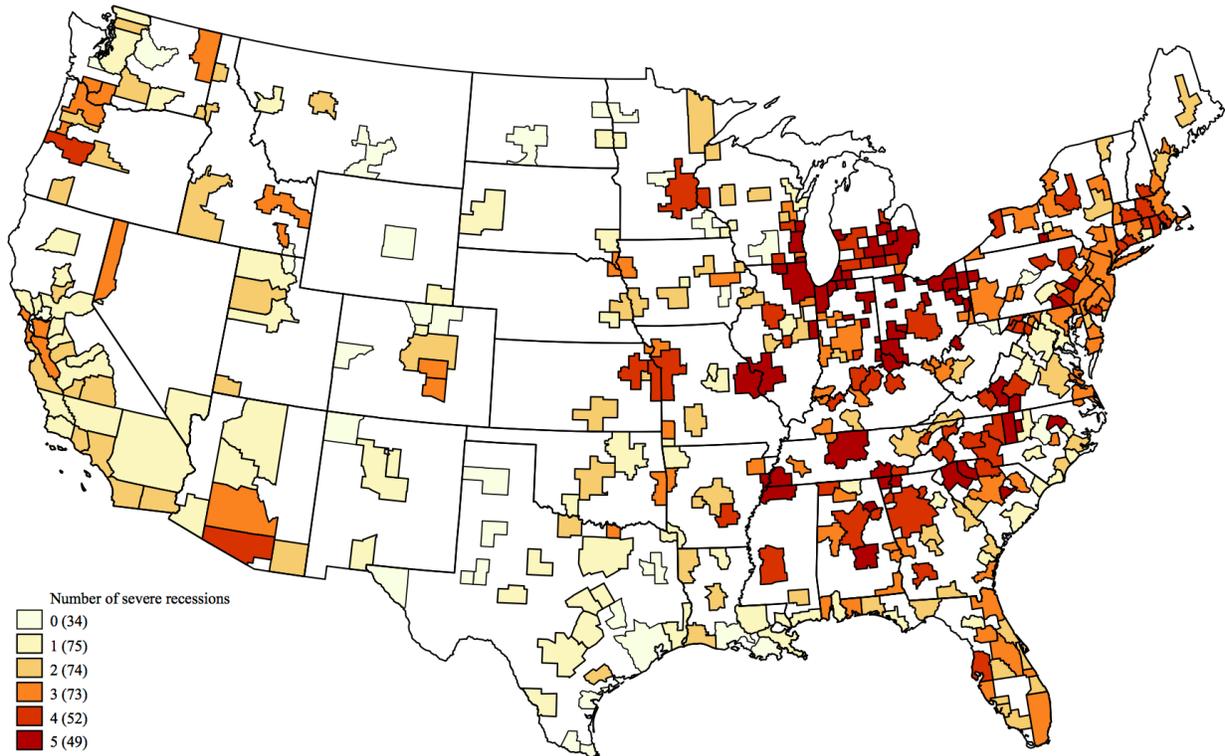

Source: Authors' calculations using Bureau of Labor Statistics Current Employment Statistics.

Figure 2: Log Employment Changes During Recessions in Metropolitan Areas

Notes: Each map shows the change in log employment from national peak to trough for 363 CBSAs (OMB vintage 2003 definitions) as described in the text. Areas in darker colors experienced larger employment losses.
 Source: Authors' calculations from BEAR.

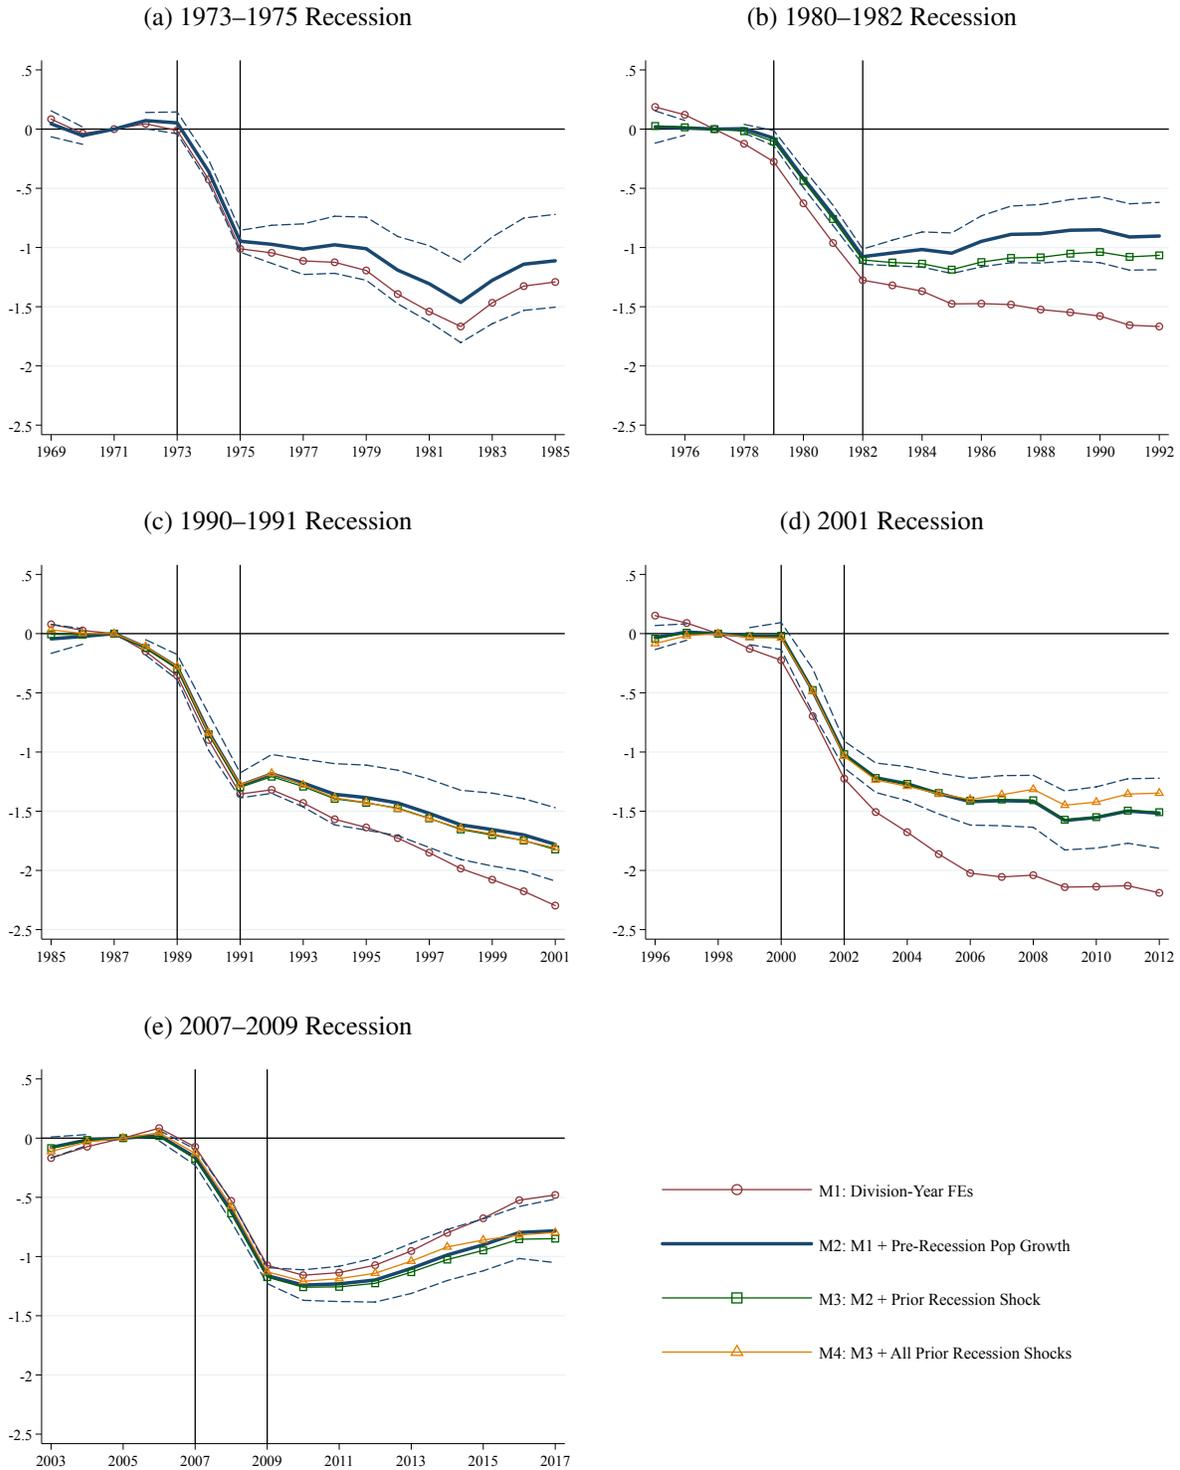

Figure 3: Frequency of Severe Recessions, by Metropolitan Area, from 1973–2009

Notes: We denote an area as suffering a severe recession if its log employment change for a given recession is less than the median across CBSAs for that recession.

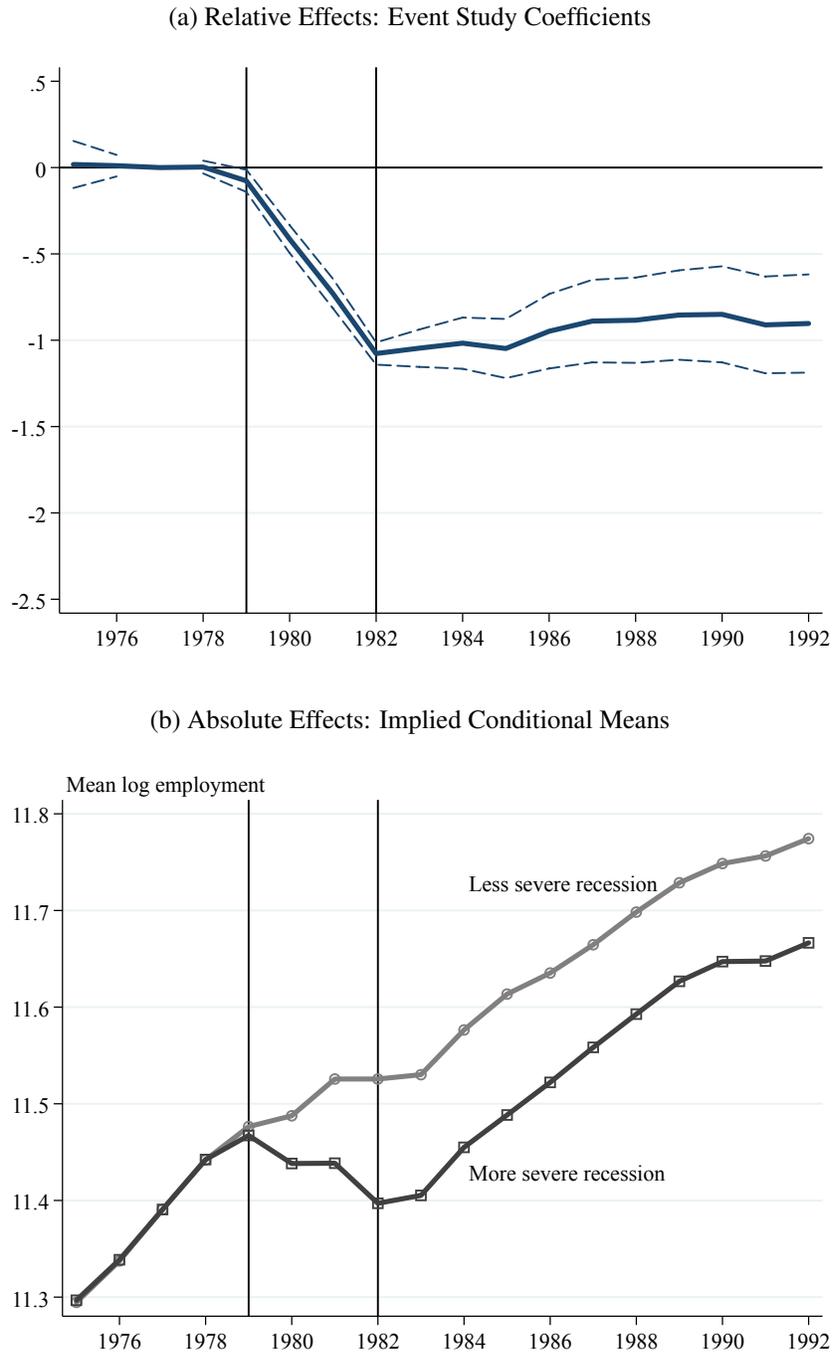

Source: Authors' calculations from BEAR.

Figure 4: Impacts of Log Employment Decreases During Recessions on Metropolitan Area Log Employment

Notes: Figure reports estimates of equation (2), separately for each recession. The dependent variable is log wage and salary employment from BEAR data, and the key independent variable is the change in log wage and salary employment during the recession from BEAR data. Specifications are indicated by the legend. There are 363 metropolitan areas in the sample. Standard errors are clustered by metropolitan area. Source: Authors' calculations using BEAR and SEER data.

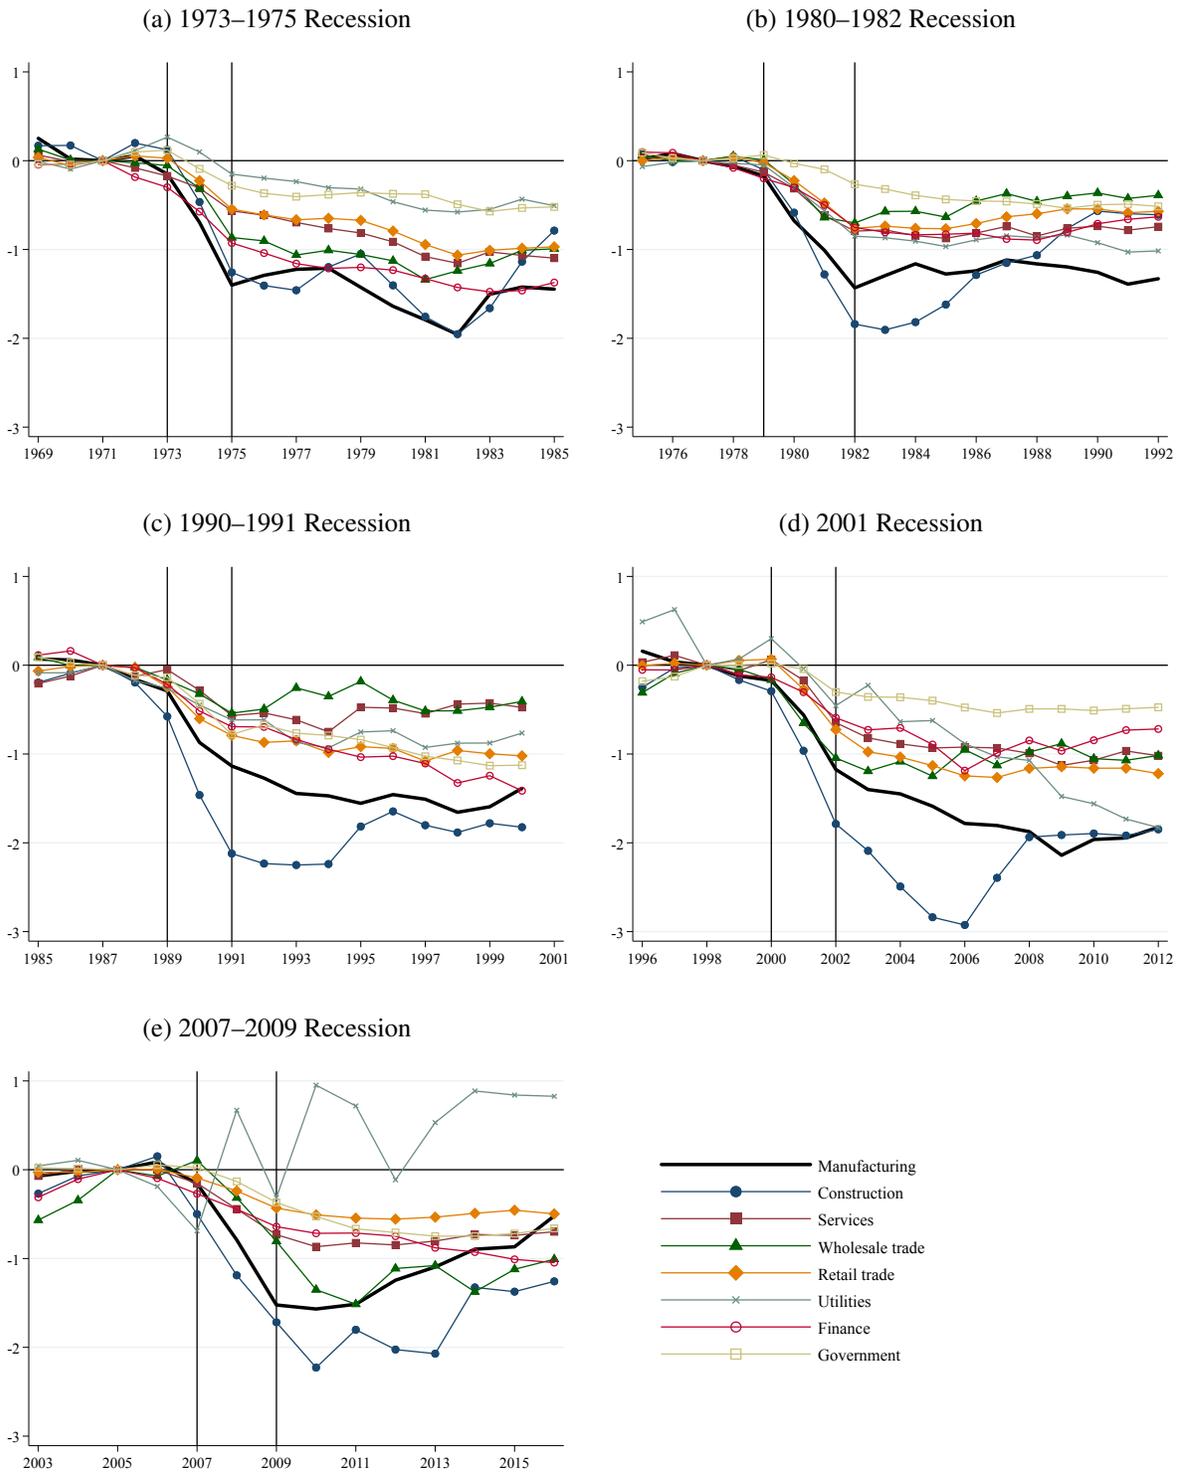

Figure 5: Comparison of Relative Effects from Event Study Regressions and Absolute Effects, Log Employment and the 1980–1982 Recession

Notes: Panel A shows estimates of event study coefficients from our main specification, as in Panel B of Figure 4. In Panel B, we use estimates of equation (2) to construct mean log employment for metro areas with a more versus less severe recession (based on whether the log employment change is greater than or less than the median log employment change during the recession), holding all other covariates in the regression at their mean value. We do this for the 1980–1982 recession for purposes of illustration.

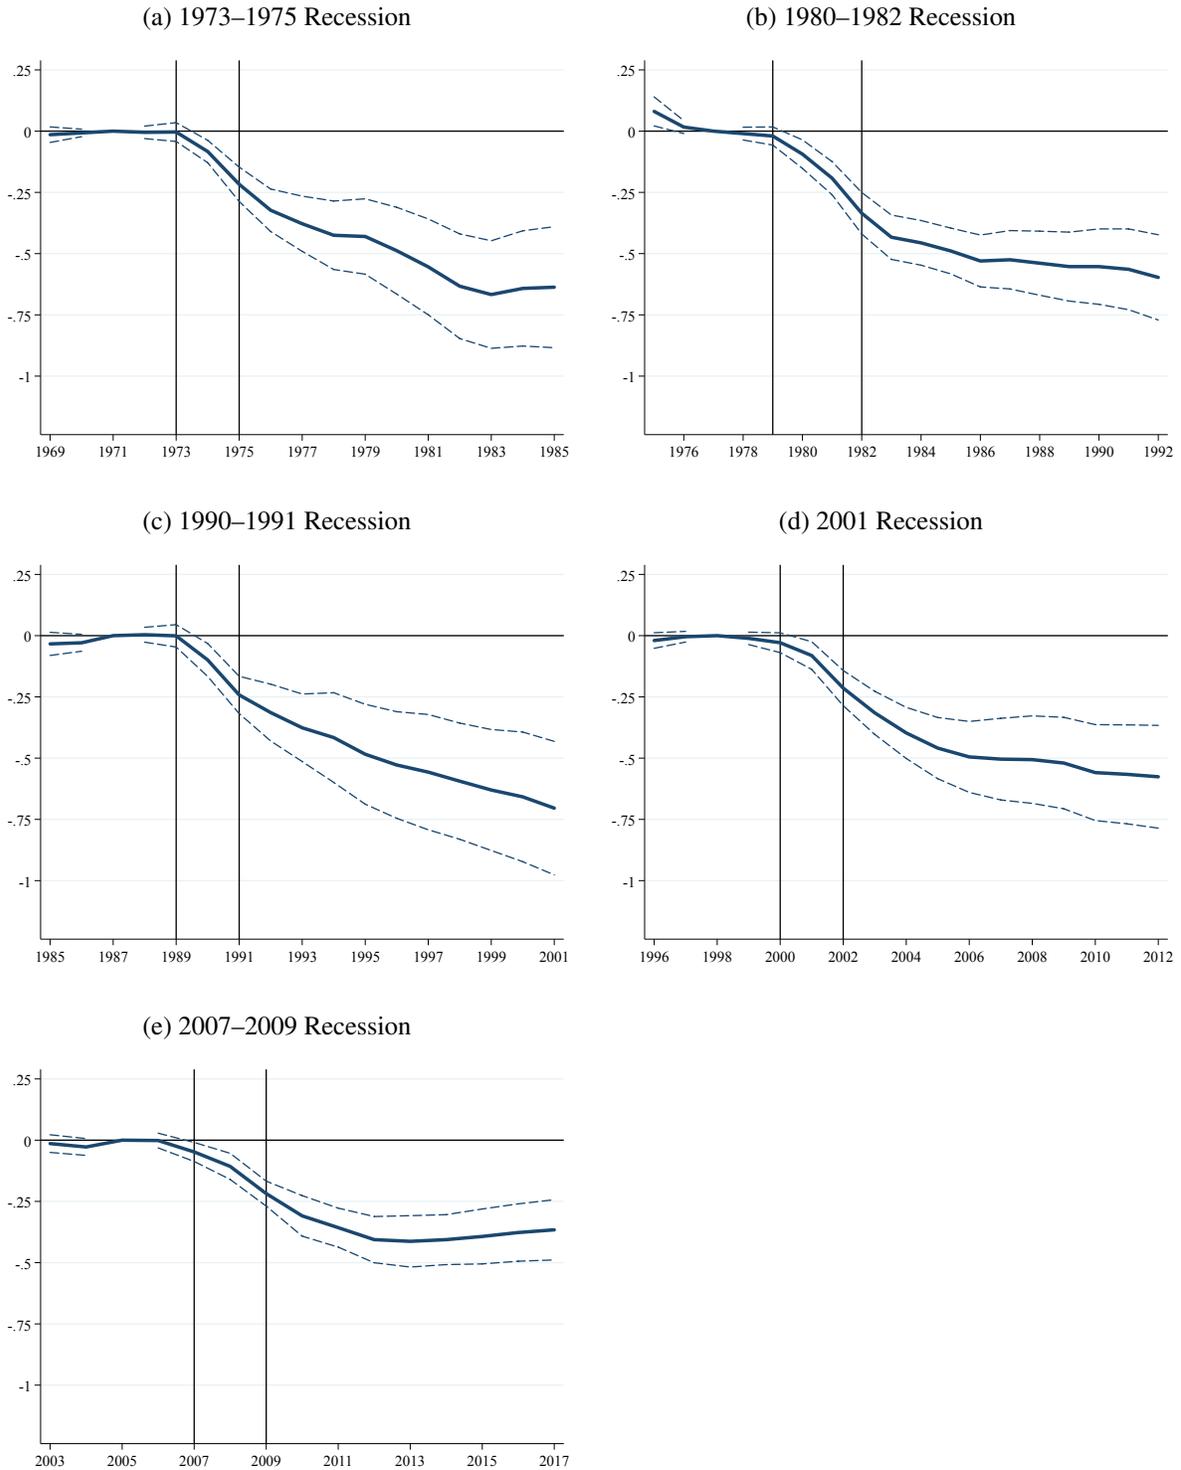

Source: Authors' calculations from BEAR data.

Figure 6: Impacts of Log Employment Decreases During Recessions on Metropolitan Area Log Employment, by Sector

Notes: Figure reports estimates of equation (2), separately for each recession. The dependent variable is log employment from the indicated sector. We use BEAR data for the 1973–75, 1980–82, 1990–91, and 2007–09 recessions. We use QCEW data for the 2001 recession (due to SIC-NAICS industry seaming issues), except for government, which comes from BEAR. See notes to Figure 4. Source: Authors' calculations using BEAR, SEER, and QCEW data.

Figure 7: Impacts of Log Employment Decreases During Recessions on Metropolitan Area Log Population Age 15+

Notes: Figure reports estimates of equation (2), separately for each recession. The dependent variable is log population age 15 and above. See notes to Figure 4.

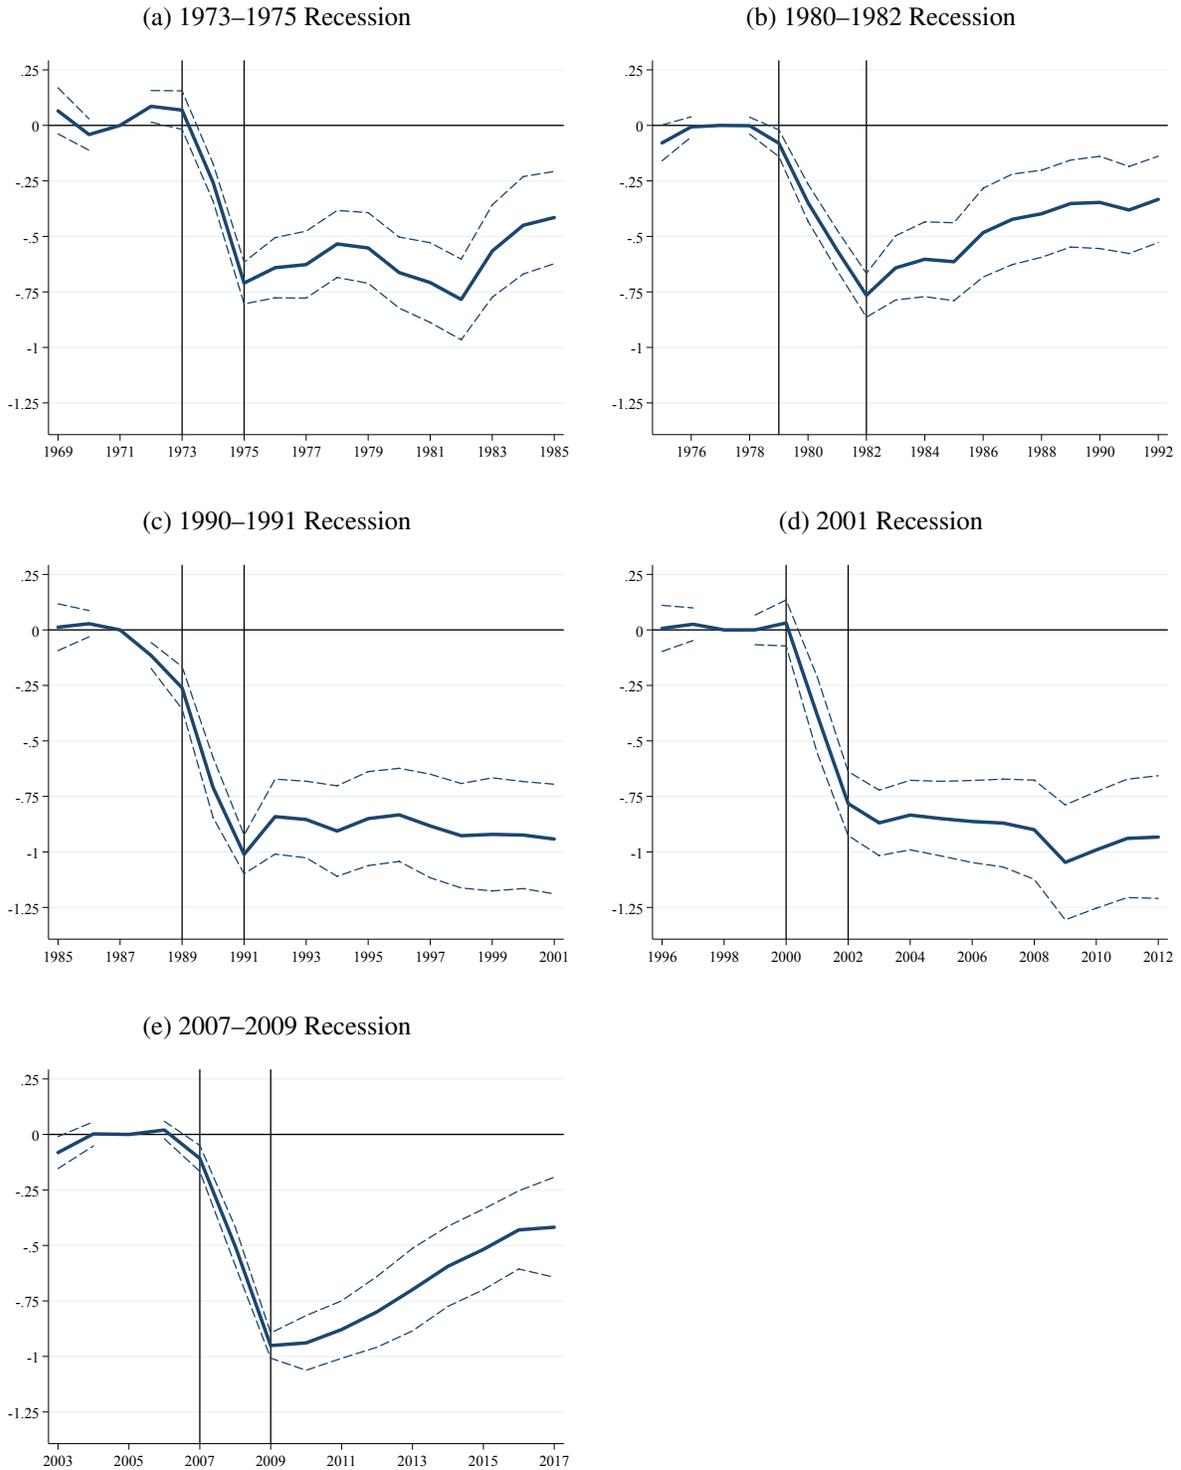

Source: Authors' calculations using BEAR and SEER data.

Figure 8: Impacts of Log Employment Decreases During Recessions on Metropolitan Area In-Migration and Out-Migration

Notes: Figure reports estimates of equation (2), separately for each recession. In Panels A and B, the dependent variable is the number of exemptions relative to the normalization year (1998 or 2005). In Panels C and D, the dependent variables are in-migration, out-migration, and residual net births, all relative to the number of exemptions in the normalization year. In Panels E and F, we divide the coefficients from Panels C and D by the coefficients in Panels A and B; we multiply the out-migration coefficient by -1 so that the shares in Panels E and F add up to one. All regressions control for interactions between the level of exemptions, in-migration, out-migration, and residual net births in the normalization year and year indicators, in addition to the baseline controls described in the notes to Figure 4. Source: Authors' calculations using CBP, BEAR, and SOI data.

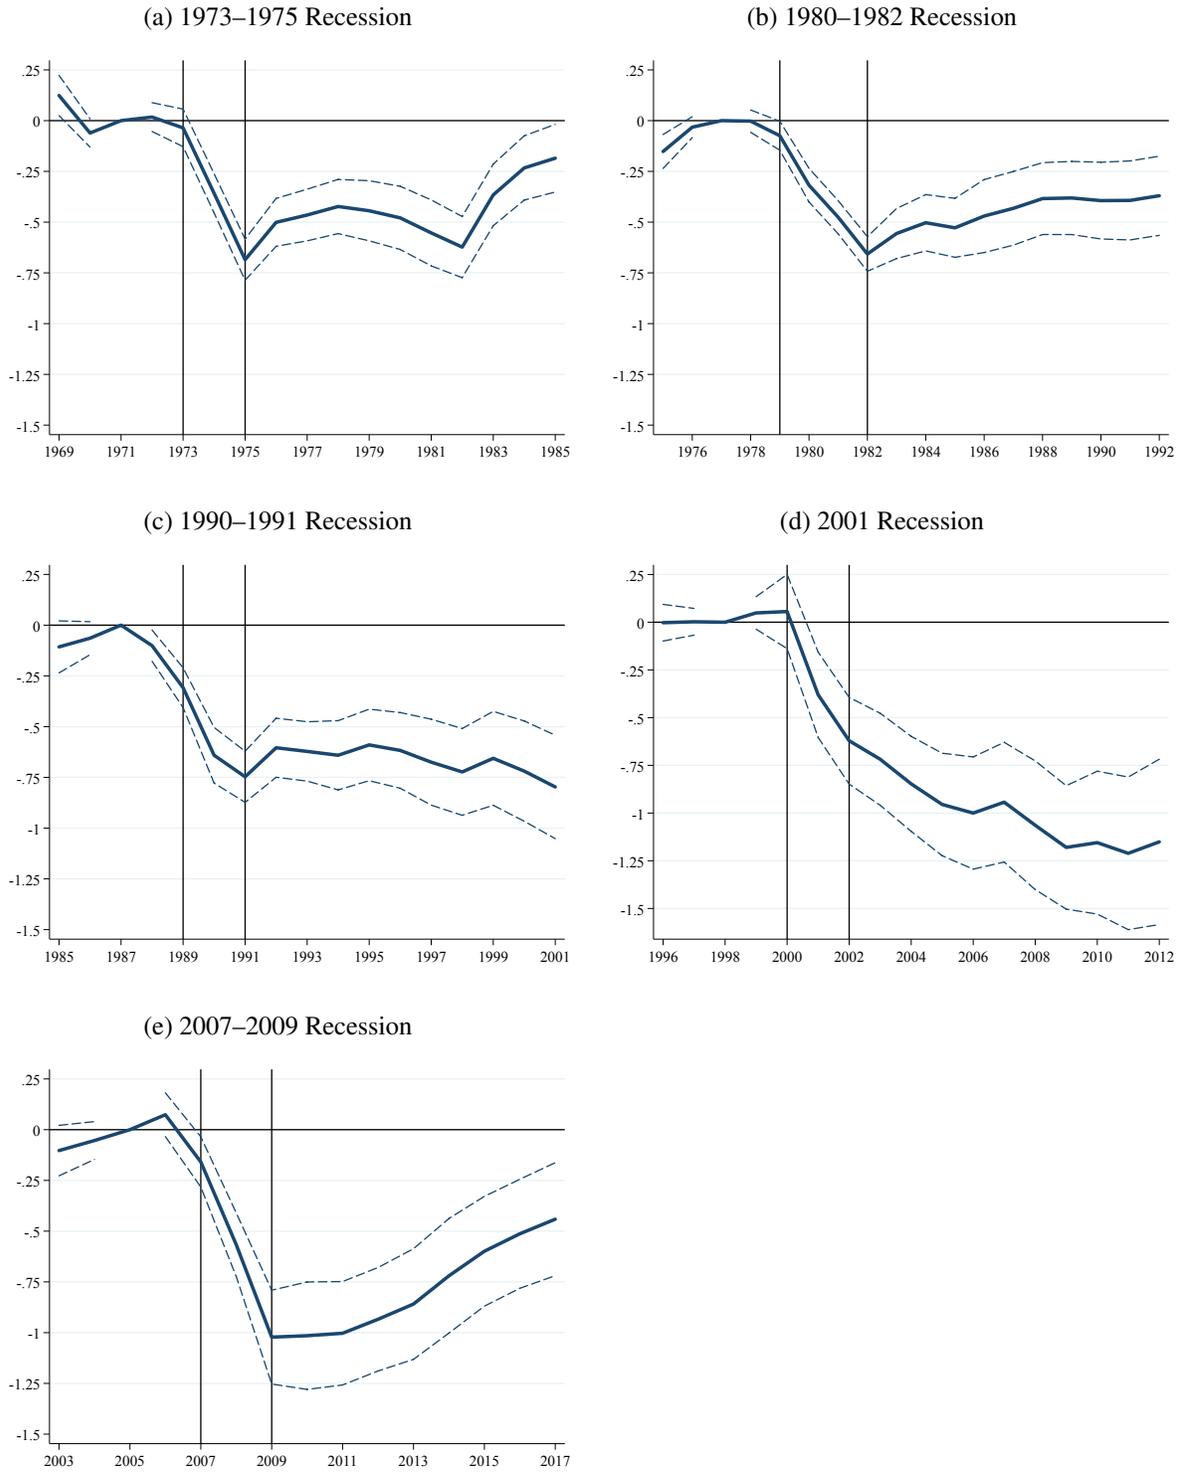

Figure 9: Impacts of Log Employment Decreases During Recessions on Metropolitan Area Log Employment-Population Ratio

Notes: Figure reports estimates of equation (2), separately for each recession. The dependent variable is the log ratio of wage and salary employment to population age 15 and above. See notes to Figure 4.

Source: Authors' calculations using BEAR and SEER data.

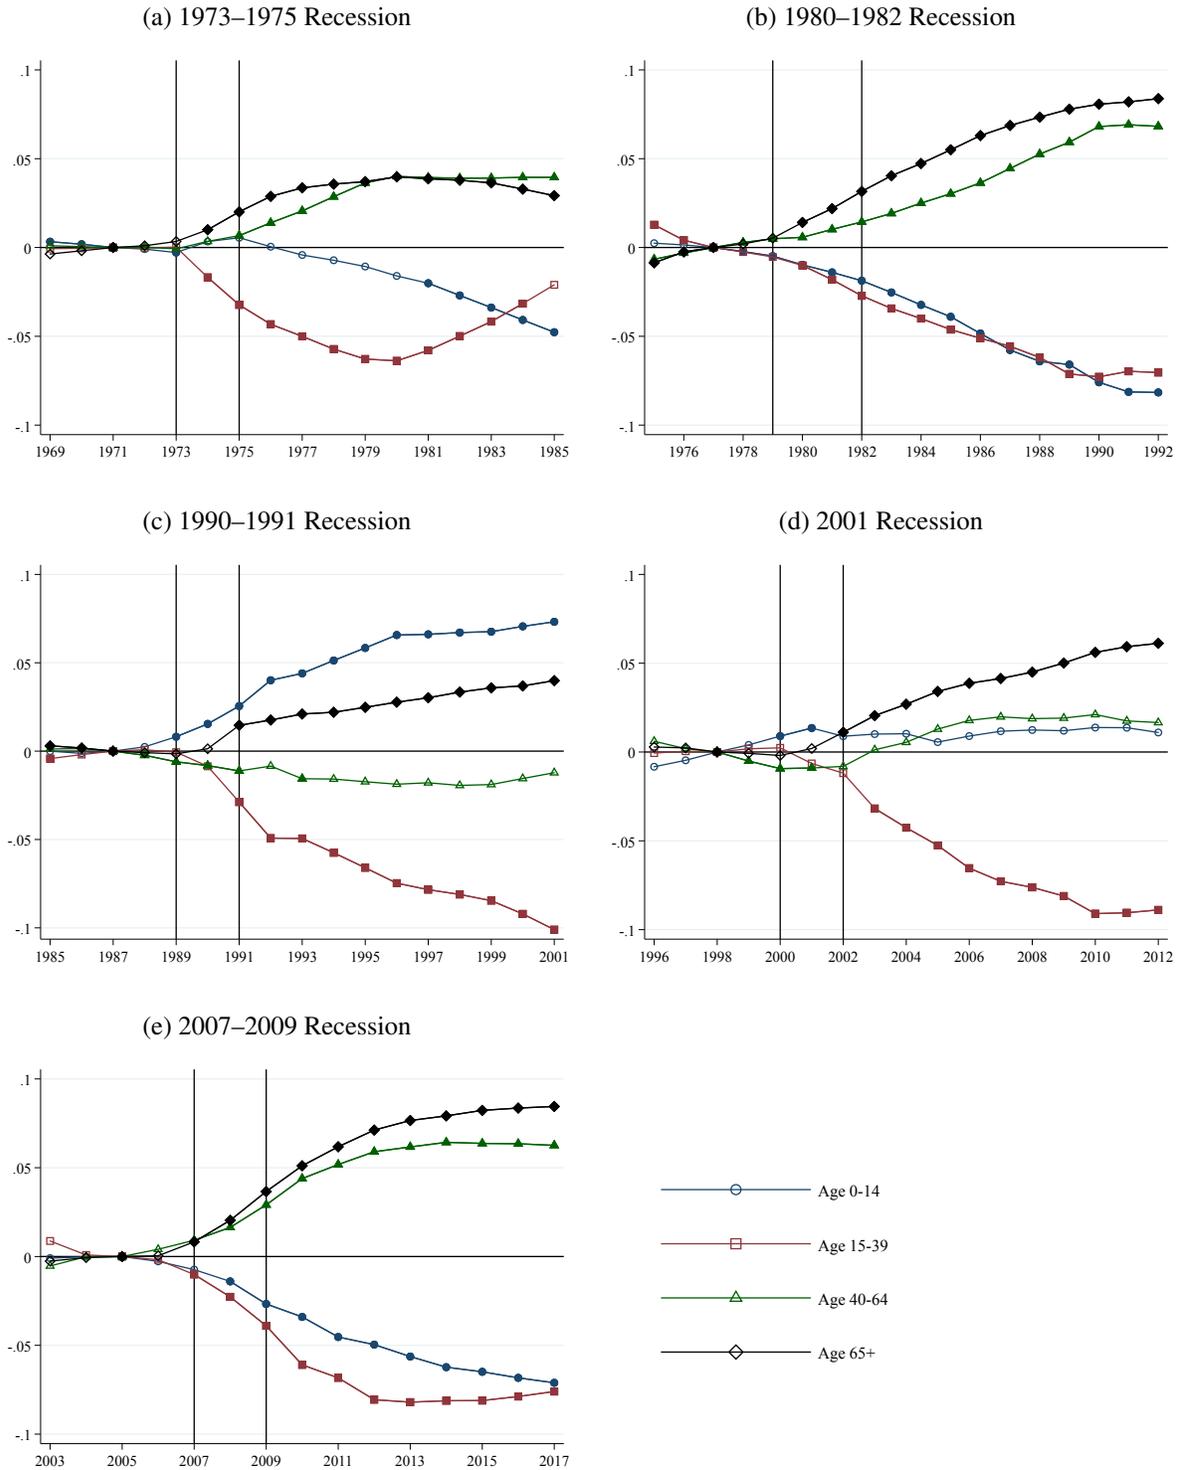

Figure 10: Impacts of Log Employment Decreases During Recessions on Metropolitan Area Log Real Earnings per Capita

Notes: Figure reports estimates of equation (2), separately for each recession. The dependent variable is log real earnings per capita (age 15+). See notes to Figure 4.

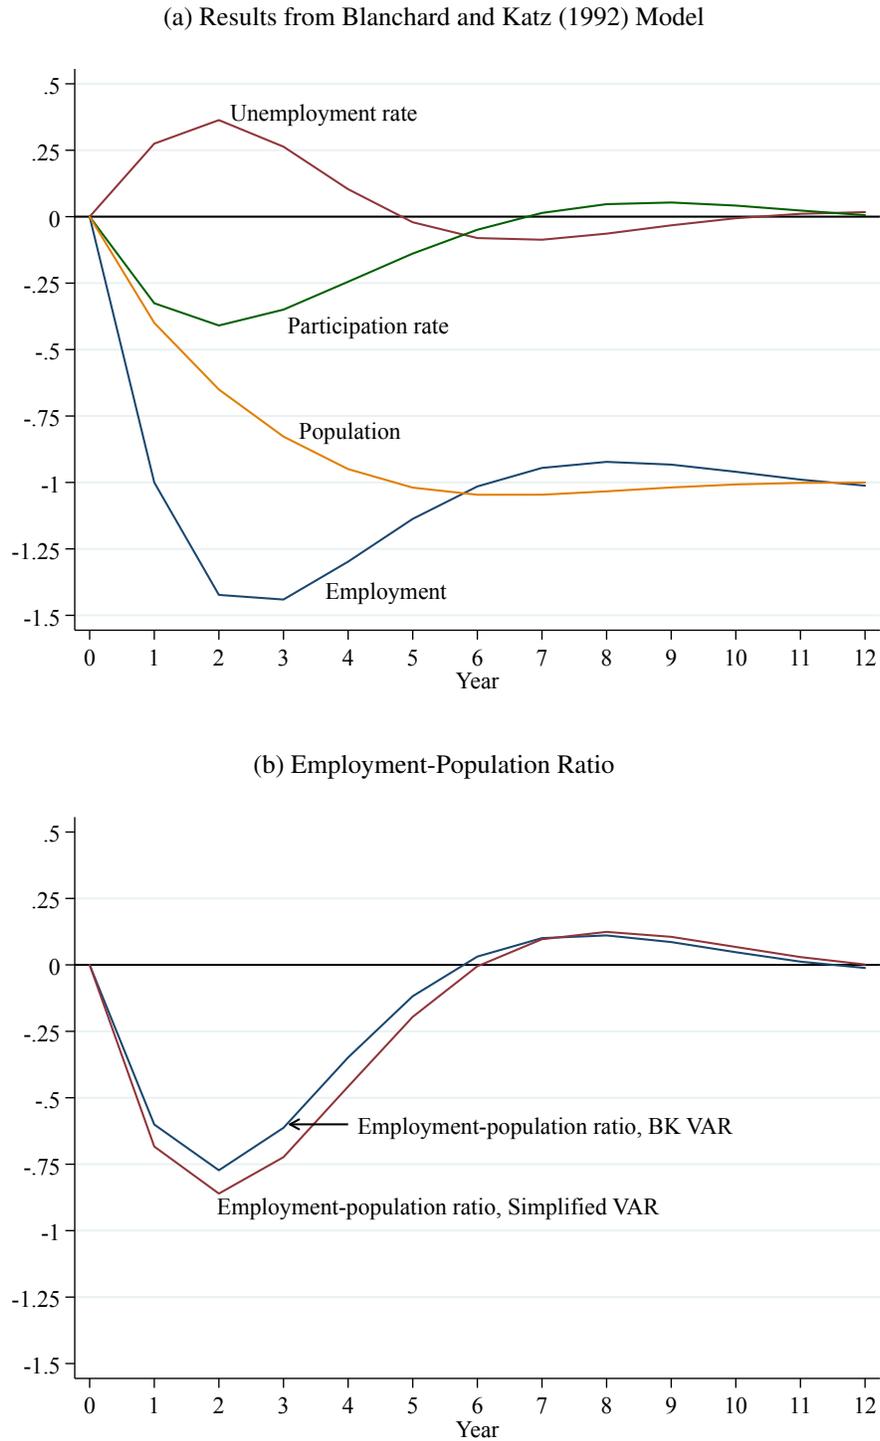

Source: Authors' calculations using BEAR and SEER data.

Figure 11: Impacts of Log Employment Decreases During Recessions on Metropolitan Area Age Structure

Notes: Figure reports estimates of equation (2), separately for each recession. The dependent variable is the share of population in the indicated age range. All regressions control for age shares in the normalization year; for other specification details, see notes to Figure 4. Filled-in markers indicate that the point estimate is significant at the 5-percent level. Source: Authors' calculations using BEAR and SEER data.

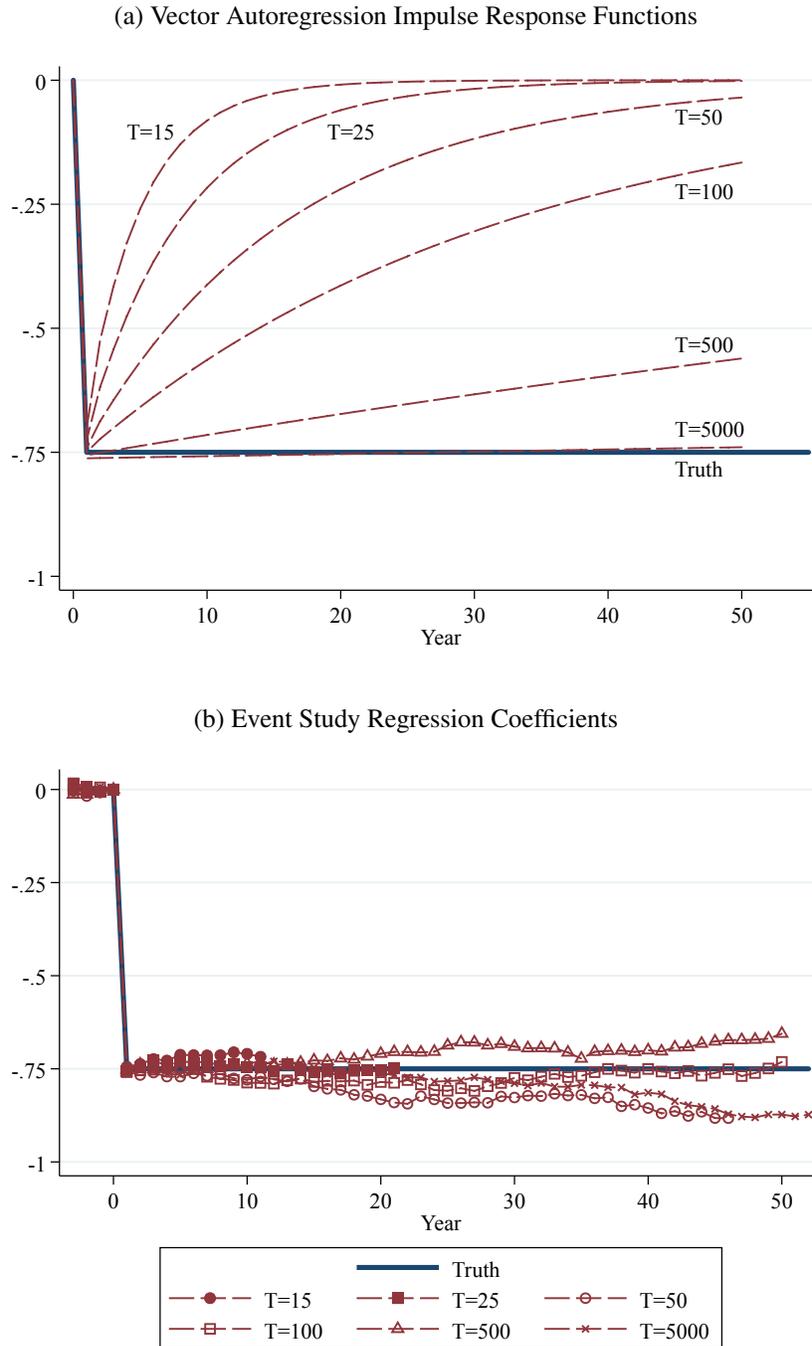

Figure 12: Impulse Response Functions to Negative Log Employment Shock from Vector Autoregressions

Notes: Figure shows impulse response functions of indicated variables with respect to a negative log employment shock. We construct impulse response functions for the BK VAR using estimates of equations (5)–(7). For the simplified VAR in Panel B, we use equations (8)–(9). Sample contains 48 continental states plus Washington, D.C. from 1976–1990.

Source: Authors' calculations using BLS LAUS data.

Figure 13: Comparison of Finite Sample Bias from Vector Autoregression Impulse Response Functions and Event Study Regressions

Notes: Panel A displays impulse response functions of the log employment–population ratio with respect to a negative log employment shock based on estimates of equations (8)–(9). Panel B displays estimates of δ_t from the event study regression in equation (16). For both panels, we simulate data following equations (13)–(15). We set $e_{i,0} \sim \mathcal{N}(13.94, 1.00^2)$, $p_{i,0} \sim \mathcal{N}(14.49, 1.02^2)$, $\varepsilon_{i,e,t} \sim \mathcal{N}(0, 0.015^2)$, $\varepsilon_{i,p,t} \sim \mathcal{N}(0, 0.015^2)$, $\phi = -0.75$, and $N = 50$. Results are based on 499 Monte Carlo simulations.

Appendices

A Data Appendix

A.1 Creating Consistent Geography Definitions over Time

We examine the impacts of recessions for different definitions of local areas: metropolitan areas and commuting zones. Each of these geography definitions changes over time. Moreover, each geography is composed of counties, and these, too, change over time.⁴² Metropolitan areas are periodically redefined by the Office of Management and Budget (OMB), and commuting zones are redefined decadal by the Department of Agriculture based on commuting questions in the Census (in 1990 and 2000) or American Community Survey (2010). For ease of interpretation, we work with temporally-fixed definitions of metro areas and commuting zones throughout our analyses. Specifically, we use Core-Based Statistical Areas (CBSAs) based on OMB definitions from June 2003 (drawn based on the 2000 Census), and commuting zones based on the 2000 Census.⁴³ Since both these geographies are composed of counties, it is straightforward to aggregate county-level data using crosswalks released by the Office of Management and Budget (via the Census Bureau) or the Department of Agriculture.

To ensure we work with consistently defined counties, we use the Census Bureau's county change database to recode county and county equivalents in the source data (BEAR, CBP, QCEW, SEER) to consistent definitions.⁴⁴ We also restrict our analytic samples to the continental United States, excluding Alaska and Hawaii. Finally, we combine the independent cities in Virginia with their surrounding counties.

For analysis using microdata from the decennial Census and ACS, counties are generally not observable. Rather, the ACS, 1990 Census, and 2000 Census contain indicators for the Public Use Microdata Area (PUMA), time-varying areas of at least 100,000 individuals. The 1970 and 1980 Censuses instead contain county-group identifiers, which are conceptually similar but based on municipal and county units rather than Census tracts. We use population-weighted crosswalks available from the Missouri Census Data Center's Geocorr application to map PUMAs to counties, and we use county group-county crosswalks available from IPUMS to map county groups to CBSAs.⁴⁵ As described in the main text, for many of the analyses we first process the microdata and then collapse the relevant measures to our analytic geographies using the crosswalks.

A.2 Imputing Employment in Quarterly Census of Employment and Wages

For some robustness checks, we use the Bureau of Labor Statistics' Quarterly Census of Employment and Wages (QCEW) as an alternative measure to the BEAR data for local area employment.

⁴²Counties are the most stable, but occasionally change due to state legislative action or boundary disputes.

⁴³See <https://www.census.gov/geographies/reference-files/time-series/demo/metro-micro/historical-delineation-files.html> and <https://www.ers.usda.gov/data-products/commuting-zones-and-labor-market-areas/>, respectively.

⁴⁴See <https://www.census.gov/programs-surveys/geography/technical-documentation/county-changes.html>. For counties that change only names or codes, we use the modern versions, and we combine counties that either merge or split.

⁴⁵See <https://usa.ipums.org/usa/volii/t1970maps.shtml> and <https://usa.ipums.org/usa/volii/ctygrp.shtml>.

QCEW data are based on unemployment insurance records from each state, are one of the inputs used by BEA to construct its employment data, and constitute the data source used to benchmark the Current Employment Statistics for monthly jobs reports. Data are available starting in 1975 from the BLS website and provide employment and establishment counts, as well as aggregate and average weekly wages, for each county and industry, at annual, quarterly, and (for employment counts) monthly frequencies.⁴⁶ However, data suppressions are common, especially earlier in the period. At the county level, data for small or highly concentrated industries (e.g., agriculture and mining) are often suppressed, although very small counties may even have total or total private employment suppressed. When these suppressions occur, *all* data for the county-industry-quarter are suppressed, unlike in County Business Patterns, described below. (For national series, used for constructing the “shifts” in the creation of predicted log employment changes as in Bartik (1991), suppression is not an issue.)

For total and total private (excluding government) employment, we impute missing employment counts at the county level through the following ordered process: 1) If total and government employment are reported but private employment is suppressed, we impute private employment as the difference between total and government;⁴⁷ 2) If either total *or* private employment is missing in a given quarter, but not for all quarters in the year, we impute the one that is missing based on the average ratio (private share of total) for the year; 3) If either total *or* private employment is missing for an entire year, such that the private share for that year is unavailable, we impute the missing values based on the average share over the rolling window from two years prior to two years after the current year. This process imputes aggregate employment counts for nearly every case from 1978 onward. For the few remaining cases, mostly before 1978, we impute values by running a county-specific regression of the log of the employment measure (either total or total private) on year and quarter dummies from 1978 forward and replacing the missing values (including those from before 1978) with their predicted values from the regression.

A.3 Imputing Employment in County Business Patterns

When constructing the predicted log employment change as in Bartik (1991), we use County Business Patterns (CBP) data to measure local industry employment shares. In the relevant years, CBP data always report establishment counts by county, industry, and establishment size, but frequently suppress employment at the county by industry level. From 1974-forward, the establishment size groups are 1–4, 5–9, 10–19, 20–49, 50–99, 100–249, 250–499, 500–999, 1000–1499, 1500–2499, 2500–4999, and 5000 or more employees.

We impute employment at the county by industry level using establishment counts and nationwide information on employment by establishment size. For establishments with fewer than 1000 employees, we impute employment as the number of establishments times average pre-recession employment in the establishment size group, where the average comes from nationwide data across all industries. We use 1999 data to construct these imputation adjustments, but the results are very similar when using other years.

⁴⁶Aggregate employment for each geography is available from 1975; industry-level measures are available under NAICS coding from 1990 forward and SIC coding from 1975 through 2000.

⁴⁷We follow this rule for 1978 forward, when local and state government reporting was near universal; prior to this year, many jobs in local and state governments were not in the reporting universe, and available counts, when not suppressed, vastly underestimated government employment. See P.L. 94-566.

Nationwide CBP data report total employment among establishments with at least 1000 employees, but not by establishment size group. To impute employment for these large establishments, we assume that employment follows a log normal distribution, with mean μ and standard deviation σ , and estimate (μ, σ) using the generalized method of moments (GMM), as in Holmes and Stevens (2002) and Stuart (2018). We estimate (μ, σ) using the following four moments:

$$p_1 = \Phi\left(\frac{\ln(1499) - \mu}{\sigma}\right) - \Phi\left(\frac{\ln(1000) - \mu}{\sigma}\right) \quad (\text{A.1})$$

$$p_2 = \Phi\left(\frac{\ln(2499) - \mu}{\sigma}\right) - \Phi\left(\frac{\ln(1500) - \mu}{\sigma}\right) \quad (\text{A.2})$$

$$p_3 = \Phi\left(\frac{\ln(4999) - \mu}{\sigma}\right) - \Phi\left(\frac{\ln(2500) - \mu}{\sigma}\right) \quad (\text{A.3})$$

$$E[y] = \exp(\mu + \sigma^2/2), \quad (\text{A.4})$$

where p_1 is the share of establishments of at least 1000 employees with 1000–1499 employees, p_2 is the share with 1500–2499 employees, p_3 is the share with 2500–4999 employees, $\Phi(\cdot)$ is the standard normal CDF, and $E[y]$ is average employment among establishments with at least 1000 employees.

We use equations (A.1)–(A.4) to estimate (μ, σ) with GMM, using the identity matrix as the weighting matrix. For years 1978, 1988, 1999, and 2006, the estimates of (μ, σ) are (7.50, 0.67), (7.49, 0.63), (7.50, 0.62), and (7.51, 0.67). We use 1999 parameters throughout for simplicity. Standard facts about the log-normal distribution imply that the imputed means for the four establishment size groups are (1249, 1950, 3373, 6679).⁴⁸

For 1999 and 2006, we can compare the county-industry employment imputations from this procedure (normalized by overall county employment to make industry shares) with those from the Upjohn Institute’s WholeData series (Bartik et al., 2019), which provides desuppressed employment counts in the NAICS period. The correlations are very high, in excess of 0.99, suggesting the imputation procedure is quite accurate.

B Results Appendix

B.1 Robustness to Different Measures of Log Employment Changes

Our baseline specification uses the change in log total wage and salary employment from BEAR to measure recession severity. We believe this variable is best because the BEA makes considerable efforts to construct data that are consistent over time, although this is more difficult for the self-employed (whose employment can vary over time in response to tax incentives). The two

⁴⁸In particular, if $\ln(y) \sim \mathcal{N}(\mu, \sigma^2)$, then

$$E(y|a < y \leq b) = E(y) \frac{\Phi(\sigma - a_0) - \Phi(\sigma - b_0)}{\Phi(b_0) - \Phi(a_0)}, \quad a_0 \equiv (\ln a - \mu)/\sigma, \quad b_0 \equiv (\ln b - \mu)/\sigma$$

$$E(y|y > a) = E(y) \frac{\Phi(\sigma - a_0)}{\Phi(-a_0)}.$$

leading alternatives are private wage and salary employment from BEAR and private wage and salary employment from QCEW.⁴⁹ Figures A.6–A.9 show that the estimated effects on employment, population, the employment-population ratio, and earnings per capita are quite similar when using these other measures to define recession severity. The similarity of the results is not surprising, as the public sector accounts for less than 25 percent of wage and salary employment on average, and BEAR data rely on QCEW data as an input. Still, it is reassuring that our results are not sensitive to this choice.

B.2 Results Using Predicted Log Employment Changes

We estimate equation (2) using OLS. A potential concern with this approach is that employment changes in local areas might stem from factors besides recessions, such as changes in labor supply. A common approach in the literature—much of which examines ten-year employment changes rather than business-cycle peak-to-troughs—is to instead use variation in log employment changes predicted by a location’s baseline industrial structure, following Bartik (1991). In our setting, the predicted log employment change is

$$b_i = \sum_j \eta_{i,j} (\ln(E_{j,t_1}) - \ln(E_{j,t_0})),$$

where $\eta_{i,j}$ is the share of employment in local area i in industry j in a base year, and the term in parentheses equals the nationwide log employment change in industry j from recession peak to trough. We use CBP data to construct $\eta_{i,j}$ (see Appendix A.3) and QCEW data to construct the nationwide log employment change.⁵⁰

We do not use the predicted log employment change in our preferred specification, because our focus on a shorter window during recessions and our controls for pre-recession population growth mitigate concerns about labor supply driving the sharp employment changes that we see. Furthermore, recent work highlights issues that arise in using industry shift-share methods (Adão, Kolesár and Morales, 2018; Kirill, Hull and Jaravel, 2018; Goldsmith-Pinkham, Sorkin and Swift, 2018). Nonetheless, given the ubiquity of the Bartik (1991) approach, we report results from using it here.

Appendix Table A.2 describes the relationship between the actual log employment change and the predicted log employment change. The first column includes no other controls. For every recession besides 1990–1991, the predicted log employment change explains 33–36 percent of the cross-metro variation in the actual log employment change. For 1990–1991, the predicted log employment change explains only six percent of the actual variation. Columns 2 and 3 add in division fixed effects and controls for lagged population growth. The coefficients—which are all positive, as expected—are reasonably stable across specifications, especially after 1973–1975 when greater industry-level detail is available. Moreover, the coefficient estimates remain highly

⁴⁹CBP data represent another alternative, although its coverage is not quite as complete as BEAR or QCEW; notably, CBP excludes most public-sector employment, as well as agricultural services, railroads, postal workers, and private households.

⁵⁰QCEW data have the advantage of being available at a quarterly frequency, which we could (but do not) use in constructing the predicted log employment change; our results are not sensitive to this choice. Because detailed county-by-industry employment counts in the QCEW are commonly suppressed, with less information with which to make imputations, we use the CBP to construct the pre-recession employment share.

statistically significant even with the additional controls.

Appendix Table A.3 shows that predicted log employment changes are more highly correlated across time than actual log employment changes. This is not surprising, as the shift-share variable primarily reflects local industry employment shares, which are relatively stable. These high correlations raise the concern that the coefficients on the predicted log employment change might not isolate the impact of a given recession. Instead, the predicted log employment change could pick up the effects of earlier or later recessions, in addition to secular changes in industry-level employment.

Appendix Figure A.10 displays estimates of the effect of the predicted log employment change on log employment. The results are qualitatively similar to those using log employment changes in Figure 4 for the 1980–1982, 2001, and 2007–2009 recessions.⁵¹ There is less evidence of a persistent employment decline for the 1973–1975 and 1990–1991 recessions; for these recessions, there is clear evidence of an employment decline during the subsequent recession, consistent with the high cross-recession correlations. Figures A.11 through A.13 display results for population, the employment-population ratio, and earnings per capita. The patterns largely mirror those for employment.

B.3 The Effects of Recessions on Commuting Zones

Our main approach defines local labor markets as metropolitan areas. Another reasonable approach is to use commuting zones, which span the entire (continental) United States, including rural areas. Appendix Figures A.14 through A.17 show that results are very similar when using commuting zones (specifically, the 2000 definition).

B.4 Back of Envelope Calculations on the Role for Productivity-Enhancing Reallocation

This appendix reports the results of simple calculations that assess whether recessions are likely to increase aggregate earnings per worker by reallocating employment to more productive areas. We refer to these calculations in the conclusion.

The change in aggregate earnings per worker due to recession-induced cross-area reallocation is

$$Y_{t+k}^C - Y_t = \sum_i (\theta_{i,t+k}^C - \theta_{i,t}) Y_{i,t}, \quad (\text{A.5})$$

where Y_t is aggregate earnings per worker in pre-recession year t , and Y_{t+k}^C is the counterfactual level of earnings per worker in year $t + k$ reflecting recession-induced employment reallocation

⁵¹There is much less cross-sectional variation in predicted log employment changes than in actual log employment changes (Appendix Figure A.1); all else equal, this would cause the coefficients on the predicted log employment change to be larger than those on the actual log employment change. However, the predicted log employment change captures only a fraction of the total variation in log employment changes, so we would not necessarily expect the magnitudes to be identical even if we normalized by the standard deviations of the employment measures.

across local labor markets. These aggregate earnings per worker terms are defined as:

$$Y_t := \sum_i \theta_{i,t} Y_{i,t} \quad (\text{A.6})$$

$$Y_{t+k}^C := \sum_i \theta_{i,t+k}^C Y_{i,t}, \quad (\text{A.7})$$

where $Y_{i,t}$ is earnings per worker in metro i in year t , $\theta_{i,t} \equiv E_{i,t}/E_t$ is the employment share of metro i in year t , and $\theta_{i,t+k}^C$ is the counterfactual employment share in year $t+k$. We construct this counterfactual employment share as

$$\theta_{i,t+k}^C = \frac{E_{i,t} \times \exp(s_i \hat{\delta}_{t+k})}{\sum_j E_{j,t} \times \exp(s_j \hat{\delta}_{t+k})}. \quad (\text{A.8})$$

The numerator of this expression is the pre-recession employment level multiplied by the percent change in employment predicted by recession severity from equation (2). Using only the employment change that is explained by recession severity ensures that we do not attribute secular changes (absorbed by our controls) to the effect of the recession.

Column 1 of Appendix Table A.6 reports the unweighted standard deviation (SD) of the difference between the counterfactual employment share and the observed pre-recession employment share, $(\theta_{i,t+k}^C - \theta_{i,t})$. We construct this counterfactual 7–9 years after the recession trough, using the estimates in Panel A of Table 4. We set t as the peak recession year. Column 2 reports the unweighted SD of the relative employment share difference, $(\theta_{i,t+k}^C - \theta_{i,t})/\theta_{i,t}$. There is a fair amount of reallocation, with the standard deviation ranging from 3.5 to 7.5 percent of baseline employment. Column 3 reports the nationwide average of mean annual earnings per worker in the peak year, expressed in constant 2017 dollars. Column 4 reports the change in aggregate earnings per worker, $Y_{t+k}^C - Y_t$. In four out of five recessions, cross-area reallocation lowers earnings per worker. However, the aggregate changes are extremely small, ranging from a reduction of \$213 (1990–1991) to an increase of \$21 (1980–1982). This is underscored in column 5, which divides column 4 by column 3 and then multiplies by 100 to express percent changes. The largest change is only 0.3 percent of peak year earnings per worker.

To shed further light on these results, Appendix Figure A.18 displays the cross-metro correlations between the employment share change $(\theta_{i,t+k}^C - \theta_{i,t})$ and peak-year earnings per worker $(Y_{i,t})$. The marker symbols are proportional to the peak year employment share. High-earning metro areas regularly lose and gain employment. On average, there is no net shift towards higher or lower earning metro areas, as seen in Table A.6.

In sum, these calculations suggest that recessions do not meaningfully reallocate employment towards more productive metro areas.

Table A.1: Impacts of Log Employment Decreases During Recessions on Metropolitan Area Annual, Weekly, and Hourly Wage Earnings, Census/ACS

	Recession				
	1973–75	1980–82	1990–91	2001	2007–09
Panel A: Without Composition Adjustment					
Log annual earnings	−0.203 (0.095)	−0.506 (0.092)	−0.124 (0.101)	−0.547 (0.104)	−0.549 (0.127)
Log weekly earnings	−0.192 (0.082)	−0.456 (0.076)	−0.107 (0.086)	−0.441 (0.087)	−0.489 (0.111)
Log hourly earnings	−0.171 (0.071)	−0.418 (0.069)	−0.114 (0.075)	−0.356 (0.078)	−0.428 (0.097)
Panel B: With Composition Adjustment					
Log annual earnings	−0.155 (0.086)	−0.333 (0.076)	−0.056 (0.081)	−0.627 (0.090)	−0.359 (0.112)

Table A.4: Impacts of Log Employment Decreases During Recessions on Metropolitan Area Age Structure, 7–9 Years after Recession Trough

	Recession				
	1973–75	1980–82	1990–91	2001	2007–09
Panel A: Coefficients on log employment decrease					
Share age 0–14	–0.034 (0.010)	–0.074 (0.011)	0.068 (0.016)	0.013 (0.015)	–0.068 (0.018)
Share age 15–39	–0.041 (0.014)	–0.071 (0.015)	–0.086 (0.020)	–0.088 (0.024)	–0.079 (0.015)
Share age 40–64	0.039 (0.009)	0.065 (0.012)	–0.018 (0.016)	0.019 (0.019)	0.064 (0.020)
Share age 65+	0.036 (0.010)	0.080 (0.011)	0.035 (0.011)	0.055 (0.014)	0.084 (0.013)
Panel B: Implied effect of a 1 SD log employment decrease					
Share age 0–14	–0.002	–0.006	0.003	0.000	–0.003
Share age 15–39	–0.002	–0.006	–0.004	–0.003	–0.003
Share age 40–64	0.002	0.005	–0.001	0.001	0.002
Share age 65+	0.002	0.006	0.002	0.002	0.003

Notes: Table reports estimates of equation (2), separately for each recession. The dependent variable is the share of population in the indicated category. All regressions control for all age shares in the normalization year, plus the covariates described in Table 4.

Source: Authors' calculations using BEAR and SEER data.

Table A.5: Bias in Vector Autoregression Parameters

	Parameter			
	$\tilde{\alpha}_{11}$	$\tilde{\alpha}_{12}$	$\tilde{\alpha}_{21}$	$\tilde{\alpha}_{22}$
Truth	0.000	0.000	0.750	1.000
Time series obs. (T)	Average estimate			
15	-0.038	-0.101	0.701	0.855
25	-0.022	-0.060	0.725	0.918
50	-0.010	-0.030	0.741	0.960
100	-0.004	-0.015	0.749	0.980
500	-0.001	-0.003	0.756	0.996
5000	0.000	0.000	0.762	1.000

Notes: Table displays average estimates of parameters in equations (8)–(9). We simulate data following equations (13)–(15). We set $e_{i,0} \sim \mathcal{N}(13.94, 1.00^2)$, $p_{i,0} \sim \mathcal{N}(14.49, 1.02^2)$, $\varepsilon_{i,e,t} \sim \mathcal{N}(0, 0.015^2)$, $\varepsilon_{i,p,t} \sim \mathcal{N}(0, 0.015^2)$, $\phi = 0.75$, and $N = 50$. Results are based on 499 Monte Carlo simulations.

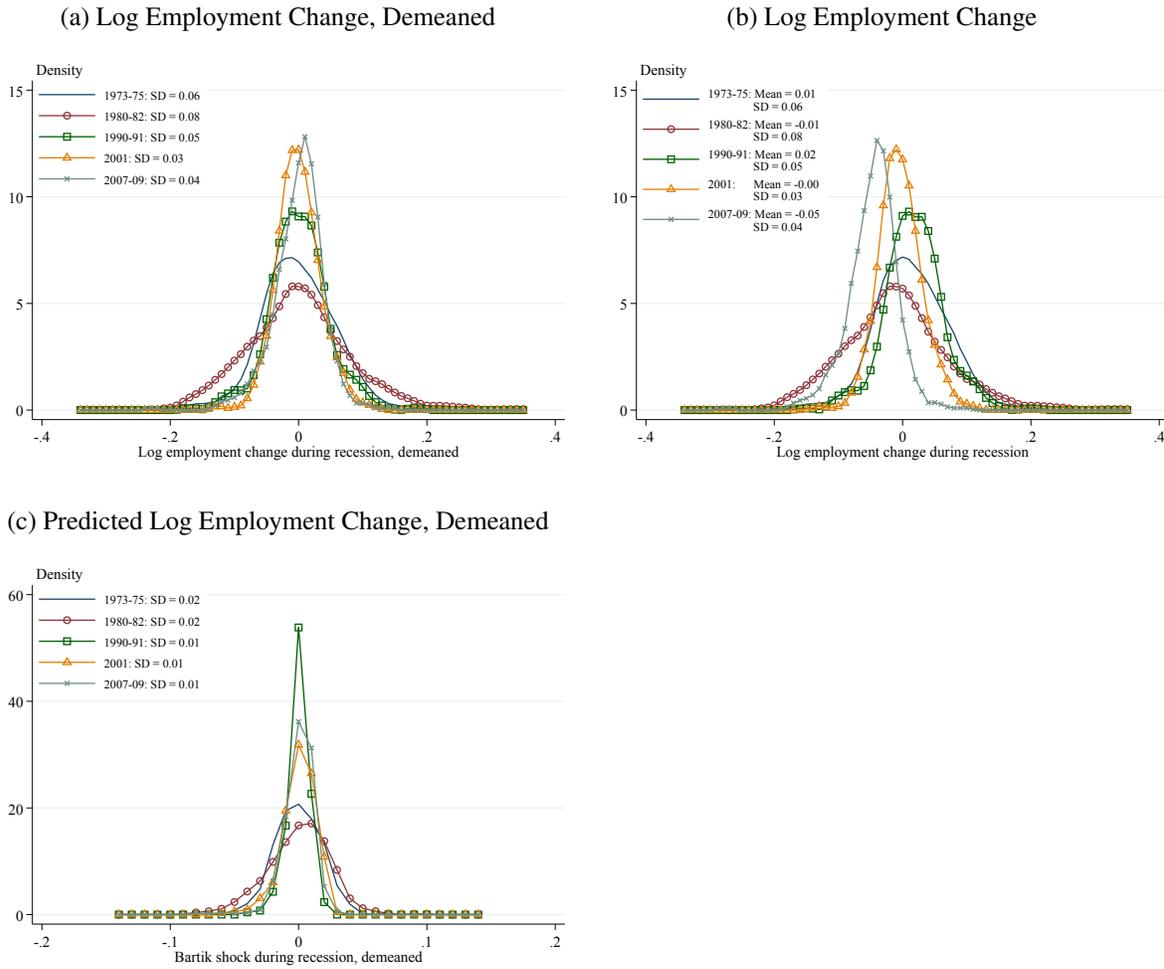

Table A.6: Changes in Earnings per Worker due to Recession-Induced Reallocation

Recession	SD, emp. share change (1)	SD, rel. emp. share change (2)	Mean earnings per worker, peak year (3)	Change in mean earnings per worker (4)	Percent change in mean earnings per worker ($\times 100$) (5)
1973–1975	0.00039	0.075	54,060	–12	–0.022
1979–1982	0.00032	0.071	54,339	21	0.038
1989–1991	0.00049	0.072	62,974	–213	–0.339
2000–2002	0.00020	0.049	76,888	–70	–0.091
2007–2009	0.00016	0.035	85,751	–1	–0.001

Notes: Column 1 reports the unweighted standard deviation of the difference between the counterfactual employment share (reflecting recession-induced employment reallocation) and the observed pre-recession employment share, $(\theta_{i,t+k}^C - \theta_{i,t})$. We construct this counterfactual 7–9 years after the recession trough, using the estimates in Panel A of Table 4. Column 2 reports the unweighted SD of the relative employment share change, $(\theta_{i,t+k}^C - \theta_{i,t})/\theta_{i,t}$. Column 4 reports the change in aggregate earnings per worker, $Y_{t+k}^C - Y_t = \sum_i (\theta_{i,t+k}^C - \theta_{i,t}) Y_{i,t}$. Column 5 divides column 4 by column 3 and then multiplies by 100 to express percent changes.
